ORIGINAL ARTICLES.

MEDICAL EDUCATION IN COLORADO.

BY S. G. BONNEY, A.M., M.D.,

OF DENVER, COL.;

DEAN OF MEDICAL DEPARTMENT AND PROFESSOR OF MEDICINE DENVER AND GROSS COLLEGE OF MEDICINE, DENVER UNIVERSITY.

IN one of the choicest essays ever contributed to medical literature, entitled "Chauvinism in Medicine," William Osler speaks of the "art of detachment as that rare and precious gift which enables one to separate himself from his environment and to take a panoramic view of the conditions under which he lives." Is it not well for the profession of Colorado employing this art of detachment, to undertake a philosophic view of its lights and shadows, its present realities and future possibilities?

The trend of the profession is directly dependent upon the thought and work of medical education. Educational influences alone mould the character, determine the proportions and direct the future of the body medical. These influences are not to be referred entirely to medical schools, but to a certain degree may be said to surround the practitioner throughout his active career, from close association with the state society and other medical organizations. To the medical educational institutions, however, there must be accorded a predominant influence upon the real tone and vigor of the profession, as well as a representation in part of its true sphere in the sociological scale. It is then to medical education in the schools of Colorado that attention may be justly directed. Unpleasant as the task may eventuate it is apparent that the time has come for the profession of the state to confront certain essential and relevant facts, and take due cognizance of their significance.

In order more clearly to appreciate our relative position it is necessary to consider at some length the general status of medical education in the United States. The real object and scope of medical schools throughout the country is of necessity changing with the varying conditions of our national civilization. The remarkable advance in medical knowledge has demanded corresponding changes in the manner and extent of imparting instruction, as exhibited in the four years' graded and systematic course of study, the increased minimum requirements for admission, the great enlargement of the curriculum by the introduction of new branches and methods of study, the increased attention to various kinds of laboratory work with opportunity afforded for the acquirement of precise scientific information capable of actual demonstration and the amplification of the hospital and dispensary facilities with the patient rather than the disease, furnishing the text and inspiration.

Up to this point the majority of the medical schools of the United States in so far as opportunities permitted, have endeavored with varying degrees of good faith and exactitude, to keep step with the onward march of medical education. Assuredly the two medical schools of Colorado have not been lacking in an earnest desire to remain "en rapport" with the recent advances and in a sustained effort to elevate the standard of higher medical education within the state. Speaking for the Denver and Gross College of Medicine, it is asserted that all the advanced methods of teaching medicine are observed in the course of study and that all provisions embodied in the curriculum in conformity with the requirements of the Association of American Medical Colleges are rigidly and conscientiously executed.

Coincident with the pedagogic advances in medicine during the past decade there have also taken place marked changes in the general sociologic and economic conditions relating to medical practice. As a result radical innovations have been inaugurated in some of the larger institutions of medical learning which have not as yet been incorporated in the medical schools of Colorado, and which may be said to constitute a vital change in the policy and purposes of all institutions adopting them. While many of these changes are directly in line with the progress of modern medical thought and are alike indicated in the interests of the medical profession, the medical student and the community, they none the less aim at the very root and life of some of the smaller institutions. An explanation of the recent agitation is found in the supposedly unhealthful conditions of medical education due to the alleged multiplicity of medical schools resulting in a so-called oligarchy and in the apparent superfluity of medical students.

It must be admitted that during the past twenty years the number of medical schools in the United States has nearly doubled, and despite the elevation of standards and higher requirements the number of students during this period has increased one hundred per cent. Billings has recently pointed out that the present average is one physician to every six hundred people, and that with the natural increase of our population together with deaths in the profession, there is reasonable opportunity based on this proportion for the accession of three thousand graduates annually. The fact exists that nearly twice this number are actually graduated and also that the proportion of one to six hundred is regrettably high.

Based upon such a showing it is to be expected

[1] Read before the Colorado State Medical Society, in Denver, October, 1904.

that the popular demand should be for fewer medical schools and fewer but better educated doctors. Accordingly the dictum virtually has been promulgated on the part of some of the larger institutions that the moral right of existence be denied some of the smaller schools. In so far as this condemnation and stamp of disapproval applies to institutions existing, not because of a valid need but flourishing as a public and professional menace, there can be no honest difference of opinion among medical educators.

With inferior teachers and entire absence of proper facilities these ventures in the past have frequently proved not unprofitable as commercial enterprises, the principle having been the maximum production at the minimum expense. Such factories unfortunately have been furnished with sufficient raw material to keep the plant in operation and foist the inferior product of the wretched machinery upon society. It is well known that the number of these bastard medical schools already has diminished materially. There remain, however, many comparatively small institutions of recognized merit and established reputations with accorded honesty of purpose and highest motives, together with suitable equipment of teachers, buildings and apparatus, and with ample clinical advantages. Some of these honorable institutions have enjoyed prolonged periods of usefulness and are now striving zealously to uphold the standard of medical education.

Their distinctive sphere and high order of working ideals is beyond question. Recognized advantages do accrue from the more intimate contact of professors and students, the close relationship permitting such interchange of thought as more perfectly to awaken incentives and inspire highest endeavor. However, it has been intimated that the life of these institutions is seriously threatened if they attempt to conform in fullest measure to the advancing standards of medical education. The reason may be ascribed to exist in the lessened revenue from tuition resulting from the diminished number of students and the greatly increased expense, both of which conditions are presupposed to obtain from the higher requirements and advancing scope of modern medical institutions. It is well to inquire more particularly into the rationale and validity of these premises.

The overcrowding of the profession incident to the multiplicity of medical schools constitutes a factor in the problem of medical education worthy of most serious thought by those who, in official positions, have to assume a portion of the responsibility in graduating classes still further to swell the ranks and increase the competition.

The responsibility of medical schools attaches to the students whom they receive and graduate, and to the community at whose doors the foundlings in medicine are wantonly abandoned. The student has the right to expect after the expenditure of considerable money and years of hard and faithful preparation, a reasonable opportunity by virtue of his training and actual fitness to provide for his family and secure ultimately a satisfactory competence. The public is entitled to the belief in the thoroughness of the student's preparation, the character of his moral attainments and the high degree of his fitness to fulfill the exacting requirements and assume the responsible obligations of his profession.

It would seem to be in line with medical progress to place such rigid restrictions upon the course of study as greatly to diminish the number of graduates and at the same time to increase their practical proficiency. Yet despite the constantly increased requirements in many of the schools, the lengthening of the course, the added cost of securing a medical education, the appreciation of the utter impossibility of attaining proficiency in all of the branches owing to the enormous mass of medical knowledge, notwithstanding, also, the repeated warnings of the profession as to the uncertainties of success in practice, there yet appears to be an actual increase in the number of students who matriculate each year. "The large number of young men who in the face of these discouragements are willing and anxious to undertake the laborious task of systematic medical study, implies a certain change in the motives and aspirations of at least a portion of the more liberally educated students of to-day. Some are anxious to begin the study of purely scientific aspects of medicine with its opportunities for original research and investigation, while others are attracted early to the possible attainment of special knowledge and skill in certain departments in the hope of teaching as a life work, or subsequent contributions to the science of medicine rather than to the practice of the art or to the acquirement of a lucrative income."[1]

This has involved the appreciation on the part of the faculty and trustees of some of our medical schools that the true province of such institutions is not simply to graduate working doctors but also to educate physicians of culture in its broadest sense, a sense by no means purely technical. It follows that the real mission of a modern medical school should be sufficiently comprehensive to provide for the rendering of post graduate instruction, and to afford opportunity for the pursuit of original research by certain of the faculty and by students who may elect so to do. One of the working ideals of such an institution should be toward the possible enlargement of the practical application of pure science, the investigation of new discoveries and the proper interpretation of new phases of medical learning.

The educative influence and the beneficence of such an institution, not only upon the profession but upon the community, is entirely beyond the powers of description. If then the purposes of a modern medical school are along the lines that have been suggested, supplementary to its traditional work of educating practising physicians, it is recognized that the fulfilment of its mission involves the necessity of fundamental changes,

[1] "Internal Medicine: To What Extend Required or Elective in the Medical Course." By the author.

though these changes need not necessarily be sufficient to effect a complete transformation in its internal economy.

Actual statistics do not show that either the revenue from tuition or the number of students is likely to diminish on account of the increased requirements for admission. It becomes apparent that the small medical schools of high standards will suffer no material loss from this cause and that the opportunities for success in practice by virtue of a desired lessened competition are not to be thus improved. As in the past it will ever remain, among the young practitioners, a simple question of the survival of the fittest. Without resorting to invidious comparisons, it may be further added that the fittest do not always emerge from the largest institutions. It is asserted then that, so far as relates to entrance requirements, the smaller schools without fear or prejudice to their own interests may cooperate to an equal degree with others in an effort to raise the present standards.

If there be perfect sincerity of purpose and earnest enthusiasm for the uplifting of medical education it is apparent that perfunctory conformity with the requirements as laid down by the Association of American Medical Colleges is insufficient for the accomplishment of the best results. Anyone at all familiar with medical educational affairs is undoubtedly impressed by the frequent evidences of laxity and bad faith concerning entrance requirements on the part of even some of our larger and apparently prosperous institutions. It is evident from the very nature of the conditions that they admit of such elastic application on the part of interested and partisan examiners as virtually to deprive them of much of their actual value. It is suggested that the examinations should be conducted by disinterested, unprejudiced and competent educators having no connection with the institution, and that there should be a uniformity of entrance requirements in different States, together with at least an approximate understanding as to the subsequent grading of instruction. This much-to-be-desired advance can best be brought about by legislative enactment placing the matter of entrance examination and systematic teaching under the control of a state board of medical examiners, acting under the supervision of and in conformity with a national organization. Such a course can in no wise lower the standards of reputable institutions that are already inspired to maintain a high order of entrance requirements, and it will surely dispense with the flexible and shameless morals of others. As to the second proposition, viz., the greatly increased expense incident to conducting a modern medical school, it must be admitted as has been suggested by others, that under the new and higher régime of medical instruction the proprietary school, save under exceptional circumstances, is greatly handicapped by lack of proper facilities in its effort to keep pace with the advances instituted by the university schools.

The actual cost necessary to provide opportunity for a legitimate medical education is increasing at a prodigious rate. In view of this it requires no prophet to show that the medical school of the future without financial assistance and support will be unable to exist if its ideals are high and its purposes progressive. Medical schools have long ceased to be a profitable business proposition, as any yearly surplus, if such exists, usually reverts to the school in the way of further equipment, and this in the face of the fact that the teachers devote time and energy unrestricted without compensation. The increasing cost of maintaining reputable and honored institutions is incident to the necessity of larger buildings with more complete laboratory equipment and apparatus. More important than this is the salary of certain of the faculty who should be compelled in progressive institutions to devote a large portion if not all of their time to the school. This, of course, refers more particularly to those teaching some of the scientific branches of the first and the second year. The nature of the work demanded in the various laboratories is such as to command the undivided time of the teacher and entitle him to a just compensation according to his ability and attainments. There can be no question that the success and usefulness of any school will depend to a large extent upon the character of the scientific work in the early part of the course, and this involves a large outlay for experienced and competent instructors devoting their entire time to their several duties. The number of such instructors is necessarily larger, in proportion to the number of students, than formerly on account of the necessity for individual or group teaching.

For the foregoing reasons it must be clear that in order to meet the demands imposed by the changed conditions of medical education, relief must be sought in one or two ways, first, from a close university connection, or second, if the autonomy of the medical school is to be preserved, by provision for its separate endowment. As to the matter of university affiliation, the real value to the medical school in this connection consists in the substantial aid resulting from the closeness of the relations, the control of the financial affairs, the assumption of the obligations and the guarantee of the future. Thus it is that nestling under the wing of *bona fide* universities offers to the medical school its protection, its most complete usefulness and its greatest permanency.

Nominal connection with a university avails nothing and passes for what it is really worth, a cheap subterfuge. In what way does it profit a medical school, as suggested by Dobson, to be denominated the medical department of a university embracing in its catalogue beside its department of liberal arts, one of medicine, dentistry, pharmacy, law, music, etc., the extent of which connection is summed up by its catalogue announcement to this effect and the appearance of its presiding officer once a year to confer degrees and make an address? With each depart-

ment maintaining its separate board of trustees and in absolute control of its apparatus and finances it is difficult to perceive the influence for good resulting from such an alliance. Unless the relations are more close and mutually reciprocal with the university extending financial and moral support to the department from which it derives its largest quota of students and which furnishes the basis for its claims for prosperous usefulness, the medical school is placed in a far better position by standing substantially upon its own intrinsic merits as an institution purely of medical learning.

Another advantage resulting in an actual university connection is claimed in the opportunity offered for the so-called "telescoping" of a part of the medical studies with those of the university, thereby permitting the shortening of the time devoted to academic and medical preparation by one or two years. The manner in which it has been advocated that this be accomplished is of somewhat variable character.

This phase of the subject of university connection is of vast importance and worthy of most thoughtful consideration even in those institutions where it is easily practicable. In its fullest interpretation, viz., the conducting of the first two years of medical instruction within university walls as a part of the work for an A.B. degree, it must be recognized that it presupposes the advantages of an education purely technical, to the exclusion of that broad and liberal culture derived only from college association and training.

This conception of the early invagination of the academic and medical courses is clearly in direct opposition to the spirit claimed by its adherents, to the effect that two years' association with college men in a university is reflected in added culture and refinement accruing to medical students. If such is the effect of the university atmosphere and if it is necessary to raise the standards of admission, and if the two leading medical schools of the United States, Harvard and Johns Hopkins, have had the courage to demand a full A.B. degree based upon clinical and scientific requirements, wherein is the strength of the position taken by Rush that the preparatory training can be shortened by half and still retain the broadening influences of a college course or maintain an equal standard of excellence in its requirements? If two years' association with college students while engaged in scientific medical study and necessarily deprived of the most valuable portion of a college course is a good thing, then the entire preliminary training is surely better and productive of a higher type of education. While institutions adopting the telescoping plan are entitled to great commendation for progressive thought and action, and while their course is a distinct advance over previous requirements, the fact seems clear, nevertheless, that this position is not sustained by the argument that a part can be equal to the whole. It seems to remain a matter of reasonable doubt, however, if a shortening by one year of the time of preliminary college training might not be effected without very materially detracting from the sufficient preparation of the student for medicine. This thought is emphasized by the growing tendency to specialism rising from the popular and professional demand on account of the enormous mass of medical knowledge.

Even to these, however, it must be insisted that the chief factor in advancing the science and art of medicine has been, not only the high degree of special attainment, but also the underlying basis of broad fundamental knowledge.

As to the endowment of the medical school of the future with or without university connection, let the proposition be now advanced that there exists no moral obligation upon society greater than this. Viewed either from the standpoint of true philanthropy or mere commercial instinct there can be no more valid claim for financial support. In no other department of human endeavor have there taken place such astounding advances, with such unspeakably beneficent results as exhibited even in the past fifty years of medical progress. What accomplishment in the centuries past has so resulted in the lessening of suffering as the discovery of anesthesia? What has so lengthened the span of existence as the recognition of asepsis? Can any appeal to society savor more of pure benevolence than that which has for its purpose the saving of life and the relief of pain? In what manner has there ever occurred such preservation of communities as has resulted from the study and investigation of yellow fever, typhoid fever, diphtheria, cholera, bubonic plague and malaria? Has anything been more intensely practical than the municipal application of the principles of modern sanitation? Is there offered to society any better return upon the investment than that from which it derives its protection and permanency?

The recent achievements in medicine are sufficient, as Osler remarks, "to make even the angels rejoice," and it may be added also are all contributory to the suicide of the purely business aspects of the profession, and these have resulted from the labors of medical men with the facilities and incentives afforded by medical schools. Who can state that the final achievement has already been attained in the evolution of medical progress? Who can tell what the future has still in store as a result of further stimulation to medical science and investigation? The debt of society to medicine is indeed great and the fact that it is not more duly and fully appreciated must be construed in part to the apathy of the profession itself. Should not medical institutions justly look to the communities which are favored by their presence for an equitable measure of assistance and support?

The obligation is equally great upon the profession of any locality to extend to its reputable medical schools its legitimate aid and loyal support. It should be incumbent upon all those actively engaged in the cause of medical education to solicit financial aid for the institutions which

they represent from the wealthy with whom sufficiently close relations may be enjoyed. There can be no difficulty about the suitable endowment of these medical schools worthy of patronage provided a proper enthusiasm and an earnest devotion be manifested by its faculty.

Apropos of the foregoing remarks it may be inquired to what extent and in what manner the medical schools of Colorado, and through them the profession of the State, may profit by the thought and effort that has been exhibited by educational institutions in other States.

While the profession of Colorado may not be in a position to take the very lead in matters of medical education, it can be asserted confidently that she is abundantly able to follow in the footsteps of some of the older States. It may not be out of place to assert that already a distinct advance in medical education within the State assuredly has taken place. Two of the older medical colleges of Colorado, each of which had previously enjoyed a successful, useful and honorable career, have effected recently a harmonious consolidation, the prime motive and inspiration of which existed in a conscientious effort to elevate the working ideals of medical education in our midst. In this the beginning of its second term, one is enabled to look back upon a year of faithful endeavor, a period of unbroken harmony and perfect concord, an absolute community of interests among its faculty and an increasing influence among the profession.

What is the legitimate *raison d'être* of a medical school in Denver? Such an institution has an especial right to exist and a claim for support by virtue of the extent of higher scientific and practical work being accomplished by its faculty, its geographical position and the actual needs of the community. Denver is rapidly becoming more and more a medical center on account of its obvious climatic advantages. Thither are attracted an increasing number of highly educated physicians who previously have enjoyed special opportunities for study and research and already achieved distinction in their respective departments. There has resulted a grouping of well equipped observers, a larger corps of trained educators than can be found in any other city of this population in the United States. The character of medical educative thought and work in the city of Denver has obtained a merited national recognition. This working capital of medical culture and experience is being utilized for the benefit of young men in medicine and for society. It offers opportunity for a large number of medical students whose education in other schools located in relatively unfavorable climates has been interrupted by virtue of ill health to complete their education in Colorado and enjoy ultimately the fruits of their previous labors.

The Denver and Gross College of Medicine, although maintained under a separate charter and distinct board of trustees, enjoys, nevertheless, a close and direct affiliation with the University of Denver, from which connection material advantages constantly accrue. In order to impose greater requirements to admission and further advance the cause of medical education in line with the progress exhibited in other schools it will be necessary first to secure suitable endowment. The University of Denver, now beginning the era of her prosperity, undoubtedly will respond in the way of financial assistance, as opportunity presents itself for increasing the usefulness of her medical department and in the institution of a coherent and graded course for those contemplating medicine which will look toward the shortening of the combined academic and medical course by one year, and at the same time relieve the medical department of the expense of conducting its first year in medicine by high-salaried teachers.

There exists still another medical institution within the State, sustained partly by State aid, enjoying the patronage and backing of a strong university and possessing in this way exceptional facilities for its preparatory work of the first two years. Its greatest usefulness is curtailed largely by its mandatory location in a small community where to some extent it is deprived of clinical advantages for junior and senior students.

There is another useful and extremely successful educative institution but without a medical department, whose able corps of professors and laboratory facilities could be augmented easily to provide adequate instruction by paid teachers during the early portion of a medical course, but which would still be without the necessary clinical advantages to be found in a large city like Denver.

The thought is suggested, Is it too much to hope that in the fulness of time the relations betweeen the several institutions in Colorado could be so amicably and satisfactorily adjusted as to permit the existence of a single medical school, not necessarily in direct affiliation with any university but enjoying such close and pleasant relations with every educational institution of the State as to permit in cooperation with each, the conducting for all students of the practical clinical work of the latter part of the medical course in Denver, where alone proper facilities can be found? In this way alone can we hope to rise materially from our present level and place the educational status of the medical profession upon the plane where it can best and most truly represent the State. When the logic of time shall have sufficiently wiped out all differences and local prejudices so as to disclose clearly the wise application of one supreme allegiance, and that to the profession which we represent and whose standard we are striving to elevate, then will it be comparatively easy to secure such legislative enactment as will place the control of medical educational affairs within the hands of a State board subject to the will and approval of the profession, and then will inevitably follow a State law controlling the practice of medicine. There will then result a closer bond of union between the medical schools and the various medical societies and or-

ganizations including the many hospitals, State and municipal boards of health. Thus each being the creation and representative of the profession, a loyal devotion to its own interests would result in the appointment to all important medical offices and hospitals with reference to special fitness for administration or teaching and not as a mark of political or other preferment.

The position of the medical profession in Colorado is at this time distinctly unique, but it is within its power to assert itself by strong and mutually sympathetic effort to raise the standard of medical education and set an example which many of the older States can well afford to emulate.

A CONSIDERATION OF THE QUESTION OF DRAINAGE IN CASES OF ACUTE APPENDICITIS WITH SPREADING PERITONITIS.[1]

BY LUCIUS WALES HOTCHKISS, M.D.,
OF NEW YORK;
SURGEON, J. HOOD WRIGHT MEMORIAL HOSPITAL; JUNIOR SURGEON, ROOSEVELT HOSPITAL, NEW YORK CITY.

Although the treatment of acute appendicitis by early operation, or in the so-called interval, is highly satisfactory, a study of the statistical tables of some of our largest hospitals show, in the gangrenous and perforative forms of the disease, and in those cases in which a rapidly spreading purulent peritonitis is a complication, results which are often disappointingly bad, a high mortality and that the views of various surgeons as to proper methods of procedure are at considerable variance.

During the past nine years in a small though somewhat active emergency hospital service, the writer has been called upon to treat a number of the more serious forms of appendicitis and to struggle with the problems presented by each. In looking back over his earlier work and in trying to explain why his methods of attack and defense have gradually altered, and in trying to find out if possible why the operative mortality in his hospital service has decreased so considerably, only one conclusion can be reached. Of course it is perfectly possible for a surgeon to have a run of good fortune or to secure a long list of carefully selected cases with a very low mortality.

In an active hospital service, however, where, as a rule, the worst cases are seen, and where "late" operations are rather the rule than the exception, in justice to oneself it becomes necessary to find out how much of the improvement in results is due to good luck, and how much to good management. An examination of the records of my own operative work in appendicitis at the J. Hood Wright Hospital, for the past nine years has proven highly instructive to me, and, with the hope that it may not be entirely without interest to you, the writer asks your attention to his method and your criticism of his results in a class of cases which are everywhere taxing the best energies of surgeons.

[1] Read by invitation before the Surgical Section of the Buffalo Academy of Medicine, March 1, 1904.

From January, 1895, to January, 1903, 114 cases have come to operation in the writer's service at the above-named hospital. From 1895 to 1898, inclusive, 42 cases were operated upon, with 13 deaths, a mortality of about 31 per cent., and from 1899 to 1902, inclusive, 72 cases were operated upon, with no mortality. Whole mortality being a little less than 11½ per cent. These cases can all be verified in the hospital records and constitute an unbroken series of operations in the writer's service of four months each year, together with such odd cases as have been operated upon by him at other times in the same years at the same hospital.

During the first period from 1895 to 1899, the character of the cases was about the same as during the later period, and operation was done in every case with a view solely to the relief of the patient and not with reference to the mortality statistics of the operator or the hospital.

In going over in his mind the changes, and, as he believes, the improvements in technic, which have gradually taken place, the writer is forced to believe that in the earlier years, in the efforts to save these desperate cases, too much traumatism was unwittingly inflicted, and too little attention paid to the efforts of nature in the same direction.

In the first series of 42 operations from 1895 to 1899, 8 cases were classed as acute appendicitis, with no deaths; 3 as acute catarrhal, no mortality; 4 were chronic recurrent, no mortality; 1 an "interval" case, no mortality; 7 were acute suppurative with abscess, 1 death. One of these cases in a second acute attack was operated upon for the removal of the appendix and recovered; 7 were gangrenous with 2 deaths—1 being from acute pneumonia, in thirty-six hours. 12 were cases of rapidly advancing peritonitis with free pus in the peritoneal cavity, and of these 11 died.

In the second period from January, 1899, to January, 1903, the records show 72 cases operated upon in my service. Of these, 15 were acute; 7 were chronic; 2 were "interval" cases; 1 suppurative, no perforation; 5 suppurative with abscess; 26 gangrenous with and without perforation; 1 tuberculous; 15 gangrenous, with advancing peritonitis.

Of these 72 cases, there was a very large proportion of "late" operations and of very serious cases of the gangrenous and suppurative forms, besides the 15 cases of spreading peritonitis, to which your special attention is called.

That there was no mortality in the last class, seems to the writer suggestive at least of the attainment of a better and safer technic than in 12 similar cases of the first group wherein but one recovery is recorded. In these earlier cases the operator was conscious of striving to do all that could be done and all that generally was done by other surgeons at the time, with whose work he was familiar, and the results matched fairly well the results in other hospitals with which he was at the time connected.

At first the methods which he now employs were rejected as entirely unsafe and unsound, but

the writer has gradually been forced to abandon his original position and has amply demonstrated, at least to his own mind, the great value of the smaller incisions, of the location and removal of the appendix largely by the sense of touch, which does away with over much exposure and handling of the intestines, the free irrigation of the peritoneum with hot normal salt solution, depending upon this rather than drainage and the removal of the diseased appendix in every possible case. This radical departure, in practice, has been so gradual, that the steps cannot always be analyzed. Results seem certainly to justify the change in technic, although the writer is free to confess that not without a struggle has he accepted and adopted measures which, but a few years ago, he looked upon as dangerous and unscientific.

Modern experimental investigation has abundantly demonstrated the marvelous power of the peritoneum to deal with infection. The introduction of pure cultures of pyogenic organisms does not cause fatal peritonitis and sepsis unless there be an overwhelming dose, or the local resistance be lowered by traumatism, or the presence of an irritating foreign body. Clinical experience has repeatedly attested the truth of these experimental researches and if it were not so, abdominal surgery would long since have ceased to flourish. In acute progressive appendicitis, nature strives to wall off the diseased organ by a barrier of plastic exudate and throws out a powerful second line of defense against general infection by bringing about marked hyperleucocytosis. As Clark has well said, "the safety of the patient in the early stage of peritonitis depends not only upon the quick delivery of serum and leucocytes into the peritoneal cavity but also upon their rapid exit." "There are no blood vessels within the body," to quote the same author, "capable of such quick action in this physiologic function as those of the omentum." And further on he says "the index of lethality in experimental infections may be judged from the varying degrees of leucocytosis. Where an excessive increase is followed by a rapid decrease of leucocytosis with increasing gravity of symptoms, this indicates that the toxicity of the organisms has overcome all phagocytosis or germicidal power of the blood serum and a fatal result will ensue."

The analogy between acute infective appendicitis and the experimental introduction of germ cultures into the belly in the presence of a foreign body, is more or less perfect. Nature attempts at first to encapsulate, then to destroy, dissolve and carry away the offending body. In the case of blood clots, pus, fibrin exudate, and smaller foreign bodies, she may be fully equal to the task.

In the case of the gangrenous appendix, however, the task is, as a rule, too much for the natural physiological processes to accomplish, unaided. Under these conditions the attack of the organisms upon the defensive forces of the peritoneum, may be so sudden as to overwhelm them; or, if this does not occur they may be more gradually overcome by the rapidly increasing attacking forces battering down the first line of defenses and establishing secondary foci, from the combined action of which the secondary defenses may be overwhelmed and the patient destroyed. What then should be our method of treating these cases of advancing peritonitis, due to an infected appendix? Obviously the first thing to do is to remove the focus of infection, the appendix, and to do it in such manner as not to cripple the inherent power of the peritoneum to deal with such toxic products as must necessarily be left behind. The infected peritoneal cavity cannot be made absolutely clean by any known method, and, recognizing the fact that in removing the diseased appendix, we have removed the principal bar to recovery, we must acknowledge the inutility and the danger of attempting to obtain perfect peritoneal drainage through the medium of gauze packing between intestinal coils or by means of the drainage tube.

We are thus driven to rely upon the normal physiological power of the peritoneum to extricate us from our difficulty. The clinical work of Morris, the experimental and clinical work of Clark, and, more recently, the work of Blake and other surgeons, who are beginning to rely upon the natural protective forces of the human organism to solve the difficult problem of peritoneal drainage, should give us courage to proceed along these lines. During the past few years, the writer has grown to rely almost wholly upon the flushing of the peritoneal cavity with hot normal salt solution, rather than upon any method of external drainage. Long before its real value was appreciated he had relied upon it to combat shock in severe operations and to dilute and carry off the toxins in the various toxemias which occurred in the course of his surgical work.

A reference to the group of cases which is appended will attest the frequency and extent with which peritoneal irrigation with hot decinormal salt solution has been employed. For the past five years or more the writer has used the muscle-splitting incision of McBurney, as a method of approach in most of his cases of acute appendicitis, even in many of those accompanied by widespread suppurative peritonitis. On the whole it has proven adequate to the work; and, in connection with the Weir extension through the posterior rectus sheath, offers a sufficiently wide exposure to do most of the necessary work required. In some cases, however, where a gangrenous and suppurative process has extended up behind the colon to the region of the liver, a counter opening in the loin has been made and local drainage carried on through this. Extensive gauze packing after operation has been abandoned, and local drainage of the wound and of the site of the principal focus of infection, when deemed necessary, has been carried on by small wicks of gauze wrapped in rubber tissue. The peroxide of hydrogen solution has proven valuable in cleansing the abscess cavity about the appendix and in loosening somewhat the adhesions about the organ and in making its delivery

by touch somewhat easier. Where the appendix is retrocecal and largely retroperitoneal it can be located by the sense of touch, standing out in low relief upon the posterior wall of the cecum; its base is located by following the longitudinal bands and developed by incisions through the peritoneum on either side of it, it is then ligated, divided and delivered, working from the proximal end outward.

When free pus is found in the peritoneum no attempt is made to wall off the appendix from the rest of the cavity by pads, but the organ is delivered as rapidly as possible, largely by the sense of touch, its mesentery ligated and divided in the usual manner, and its base pulled up together with the cecum into the wound, ligated, excised, and the stump turned in by purse-string sutures, often with the addition of a Lembert stitch. After the removal of the appendix, which is accomplished with as little traumatism as possible to the surrounding intestines, the pelvic cavity, the lower abdomen, and, in many cases as much as possible of the general peritoneal cavity, is flushed thoroughly with hot decinormal salt solution, through a large tube, or by pouring in from a pitcher, until the back-flow appears fairly clean. No attempt is made to sponge the peritoneum dry and considerable fluid is always left behind. The peritoneal wound is either closed entirely, as in my later cases, and the external wound drained; or, as has been the custom in most of the earlier cases, a small cigarette drain has been passed to the appendical site and sometimes to the bottom of the pelvis. Inasmuch as nearly all the wounds from contact have become infected with the gangrenous appendix, apparently with the same organism which has caused the appendical inflammation, it cannot be considered proper to close the external wound without providing for drainage. It has become evident to the writer from a number of observations that the cigarette drain which extends into the peritoneal cavity acts mainly as an external wound drain, since he has repeatedly noticed that the peritoneal cavity outside a very small area is rapidly shut off and no longer comes within its radius of action.

Relying upon these observations the drain has practically been eliminated as a factor of any importance in the treatment of spreading peritonitis, except in so far as it acts as a drain for the external wound, which, in most of these cases, is an infected wound and heals by granulation. The paper of Clark and Norris, on "Peritoneal Saline Infusions in Abdominal Operations," combining as it does the results of clinical study and laboratory experiment, draws the following conclusions: First, the use of salt infusions does not increase, but unquestionably minimizes the danger of pyogenic infection. Second, in addition to reduction of mortality, the convalescence of the patient is rendered infinitely more comfortable and satisfactory through the reduction of thirst, the increase in the urinary excretion and the minimizing of vesical irritation. With these conclusions the clinical experience of the writer entirely agrees. Long ago we have noticed in patients who have had saline infusions either by the vein, the rectum or the abdominal route or by hypodermoclysis, a very rapid disappearance of the odor of ether from the breath, and marked increase in the urinary secretion. The after-treatment of cases of spreading peritonitis is of the greatest importance, and upon the faithfulness and the intelligence with which it is carried out the life of the patient depends. As a routine measure, the stomach is washed out thoroughly before the patient has left the operating table and one or more ounces of the saturated solution of Epsom salts is introduced through the tube and allowed to remain. The rectal tube is passed at the end of six hours and a simple enema or an enema of salt solution is given. Opium is not used.

For the discomfort, dyspnea and distress, due to abdominal distention and upward pressure upon the diaphragm, elevation of the head of the bed may give relief, or this, in connection with gastric lavage, will often tide the patient over the first few hours of suffering. Enemata at intervals of six hours are used as a routine measure for the first two or three days, and an attempt is made to secure a passage of gas or a movement within the first twenty-four hours. Persistent distention is combated by the stomach tube through which Epsom salts may occasionally be introduced, and by enemata of oxgall, repeated as may be necessary.

The possibility of early intestinal obstruction should always be remembered in these cases of persistent vomiting and in several such cases which have been under my notice an exploratory operation has revealed this condition, and relief obtained by removal of the obstruction, which is generally due to a band, volvulus, or kinking of the gut.

Of course, when the toxins are diluted by the saline irrigation and hurried into the blood stream, a tremendous strain is brought upon all of the excretory organs, and in those cases where the kidney function is badly impaired by previous disease, an important avenue of elimination is at once removed and the patient frequently succumbs. Three cases of this sort have come within my own experience and all have died.

In one of the series of cases herein reported, secondary collections of pus formed during convalescence and required two later operations. The same complication has been observed by the writer in four or more other cases not reported in this paper.

In each instance, however, this probably could not have been prevented by gauze packing or drainage since in these very cases the additional exposure and handling would, in the opinion of the writer, have been sufficient to destroy all prospect of recovery, which eventually took place in every case, after one or more additional operations. It has been noted also that intestinal obstruction has occurred in several cases under the

same conditions and while it had formerly been my belief that most of these cases are caused by wide gauze packing between intestinal coils, I am forced to the conclusion that the condition perhaps quite often occurs in cases where no gauze drainage has been employed and is due then rather to the extent, character and intensity of the original peritonitis.

Eight cases of this complication have come under my care, and in seven recovery has taken place. The fatal case was one of very early obstruction with advancing peritonitis and sepsis which was uncontrolled by operation. Four of these cases formed the basis of a paper read by me before the N. Y. Surgical Society in 1901. In reviewing the cases of spreading peritonitis herein reported, attention is called to the fact that the term is applied only to those cases in which free purulent fluid was found in the peritoneal cavity. I agree entirely with Blake in his statement that the classification of purulent peritonitis, based upon the specific nature of the bacterial invasion, is not so important, from a practical standpoint, as that based upon the progress and extent of involvement of the peritoneum. It will be found on looking over the histories of the fifteen cases of spreading peritonitis which form the basis of this paper, that the extent of the peritoneal involvement varies rather widely. In five, which may fairly be classed as cases of diffuse peritonitis, the limits of the inflammatory process were not definable.

In four, as where the operation was done earlier, the peritonitis though more or less extensive had fairly definable limits; while in six, the pus was practically limited to the pelvis and right lower abdomen. These latter are the simpler cases and should have, ordinarily, a lower percentage of mortality. It should be noticed also that the appendix was removed in every case. This I have found easier to accomplish with growing experience in the cultivation of the sense of touch in locating and freeing the organ.

It is surprising how much can be accomplished in this matter through a comparatively small incision, and with what very little traumatism to the adjacent intestines. Upon this method of procedure, in fact, the writer has come largely to rely for the performance of rapid and effective work, and regards it as a most important factor in the technic of the operation.

In conclusion the writer wishes expressly to disclaim any originality of method or to intimate that there is anything remarkable in his results. The series of consecutive cases which are used have been taken from the records of a single hospital, where fairly uniform conditions prevailed. During this same period, however, similar methods have been constantly employed in other hospitals and in private work with increasing confidence, and the writer has every reason to feel strengthened in his position with widening experience.

The good results, may, in a measure, be due to the fact that all the patients were young, or at least comparatively so. All but three were males. Seven were twelve years or under, five were between eighteen and thirty years, two were thirty-eight years and one forty-one years old, a general average of 15.4 years.

One of the facts which has most impressed the writer, is the shortening of the period of hospital treatment. In the 23 cases operated upon in 1902, for example, the average duration of hospital care was twenty days, and all of these cases, except two interval operations, were acute, and most of them gangrenous or suppurative. The average duration of hospital treatment in the 15 cases of spreading peritonitis, excluding the second period of the second case which was readmitted and operated upon a second time, was 24¼ days. That is to say, the length of hospital treatment in these latter cases is nearly three weeks less than when the wider incisions, the gauze packing and drainage were in vogue. This feature alone, is one of the greatest economic importance both to the patient and to the hospital.

REPORTS OF CASES.

Case I. Gangrenous Appendicitis. Spreading Suppurative Peritonitis.—Wm. E., eight years of age; admitted Feb. 20, 1899. Attack one year ago, occasional attacks of pain since. Acute sudden seizure twenty-four hours ago. Examination: General tenderness, rigidity, no mass. Temperature 101.6° F., pulse, 100; respiration, 30. Immediate operation.

Operation.—Incision, McBurney's over appendix. Free pus escaped on opening peritoneum, wound extended through posterior sheath of rectus. Partial evisceration. Appendix four inches long, perforated, gangrenous, with stricture near base and containing fecal concretions. Ligated and removed; field cleaned with hydrogen peroxide solution and flushed with decinormal salt solution. Pelvis, which was filled with free pus, washed clear with saline solution, left side of peritoneal cavity showed serous fluid only. Peritoneal cavity flushed with hot saline solution, cigarette drains of gauze wrapped in rubber tissue inserted. One to the under surface of the right lobe of the liver, another into the pelvis and a third to the appendical site. Upper and lower drains removed next day. Feb. 22, appendicular drain pulled out, discharge foul odor. Wound sutures cut and a drainage tube inserted. Tube removed Feb. 26, wound rapidly cleaned, patient discharged cured March 23, 1899. Thirty-one days.

Case II. Gangrenous Appendicitis. Spreading Peritonitis. Secondary Abscess. Secondary Operations. Subphrenic Abscess.—Male, eleven years of age; admitted April 3, 1899. First attack—one week duration—acute onset—after fall upon abdomen. Examination: Abdomen generally distended, condition very bad. Temperature 101° F., pulse 128.

Operation by Dr. Le Boutillier in my absence. Oblique incision revealed large amount of free pus in peritoneal cavity, a localized abscess about

the appendix, and the pelvic cavity filled with foul-smelling pus. Appendix about three inches long, gangrenous, perforated, and containing fecal concretions. Ligated and removed. After cleansing pelvic cavity with hydrogen peroxide and flushing clean with hot saline, the general peritoneal cavity was flushed with hot salt solution and the wound closed after inserting two cigarette drains passing to the pelvis and appendical site. Profound shock, free stimulation.

April 5, delirious; temperature 102° F., pulse 140. April 6, better; wicks removed, bowels moved in response to enemata. Slow, steady improvement after this, up to April 16, when temperature began to rise without any apparent reason from condition of wound and without local signs within abdomen. April 30, temperature still elevated. Passed under the care of colleague by whom he was discharged April 26, somewhat improved, but still in poor condition and having a daily rise of temperature. Readmitted May 30, complaining of increasing pain in right side and with a swelling under free edge of right ribs. Temperature 103° F., pulse 140; respiration 126.

May 31, 1899, operation by Dr. Parker. Small incision into abscess, wound packed with gauze. Temperature fell, did well for a time, but evidence of retention of pus occurring, a second operation was performed by Dr. Le Boutillier. A large subphrenic abscess was thoroughly explored and drained. Wound closed by granulation and patient was discharged cured July 26, 1899.

Case III. Gangrenous Appendicitis. Spreading Suppurative Peritonitis. Intestinal Obstruction, Third Week. Operation. Recovery.—Male, twenty-six years old; admitted Feb. 5, 1890. Acute onset; sixth day of disease. Abdominal distention appeared, and patient looked very ill, skin cool and clammy, face pinched and somewhat cyanotic. Sent at once to hospital in ambulance, and operated upon as soon as preparations could be made. Temperature 99.4° F.; pulse, 84; respiration, 40.

Examination.—Abdomen rather distended and generally tender. Operation.—Oblique incision over appendical site reveals free thin pus, filling the pelvis and lower abdomen. Appendix long, angulated, two fecal concretions at end, and an area of gangrene with a small perforation near the middle. Cigarette drain to pelvis and appendical site, after thorough flushing of peritoneum with hot saline solution. Wound loosely sutured. Feb. 6, distention continues but high enema brings away gas and gives relief; Feb. 7, vomited; distinct fecal odor to the vomit. Stomach washed out and one ounce of saturated solution of Epsom salts left in the stomach by the tube, a high oxgall enema given later brought away gas; Feb. 8, distention somewhat less, wick drains removed, enemata continued. Convalescence uninterrupted until Feb. 21, when, sitting up in bed and taking solid food he began to have cramps and the next day vomited considerably. Feb. 24, obstruction complete, vomiting becoming fecal.

February 24, operation; stomach first washed out and median laparotomy performed; a band of adherent omentum constricting a loop of small intestine was found and divided. The peritoneal cavity was washed with hot saline solution of which a considerable quantity was allowed to remain, and the wound was closed. Immediate improvement and uninterrupted convalescence, discharged cured March 19, 1900. Forty-two days.

Case IV. Perforative Appendicitis. Spreading Peritonitis.—Male, aged thirty-eight years; admitted March 21, 1900. Several preceding mild attacks. Present seizure, acute and of twenty-four hours' duration. Examination, abdomen slightly distended, rigidity and tenderness, no tumor. Immediate operation.

Operation.—McBurney's incision, enlarged by extension through posterior sheath of rectus. Free thin pus in peritoneum. Appendix small with perforation near its middle. Excised and stump invaginated by purse-string suture. Pelvis found filled with thin pus and the intestines in the lower segment of abdomen were conjested and bathed in same. There was no fibrin present. After cleansing the principal infection focus with hydrogen peroxide and saline solution the lower portion of the abdominal cavity and pelvis was flushed with the hot salt normal saline, and a cigarette drain passed to the bottom of the pelvis. Loose suture of wound to the drain.

March 22, drain removed, stomach washed out, and a saturated solution of Epsom salts introduced through tube and left. Distention grew less and the convalescence though somewhat complicated by a moderately severe bronchitis, was, after the first forty-eight hours, uneventful. Patient discharged from hospital cured, April 7, 1900. Seventeen days.

Case V. Acute Gangrenous Appendicitis. Spreading Peritonitis.—Male, aged twelve years; admitted April 1, 1900. Indefinite history of mild attacks during the past year. Present seizure acute, with chill on day of admission. Examination general abdominal tenderness, no tumor. Temperature 102° F.; pulse, 96; respiration, 20. Immediate operation 10 P.M.

Operation.—McBurney incision. Free escape of thin, yellow free pus on opening peritoneum. Appendix lying to the inner side of cecum is five inches long, coiled spirally up on itself, no perforation. Lumen contains one large and several smaller concretions. Mucosa of tip and middle, gangrenous, proximal end of appendix normal. No limiting adhesions. Appendical region disinfected with hydrogen peroxide and flushed with saline solution. Appendix excised and stump turned in by purse-string suture. Wound loosely closed to small cigarette drain which passed to pelvis. April 3, 1900, wick out; April 5, suture out. Mild external wound infection. Discharged cured, April 20, 1900. Eighteen days.

Case VI. Gangrenous Appendicitis. Spreading Peritonitis.—Male, five years old; admitted April 22, 1900. First attack, sick one week.

Slight abdominal distention, rigidity, and tender mass in right side, condition poor. Temperature 100° F.; pulse, 120; respiration, 28.

Operation.—April 22; McBurney incision, later extended upward. Large abscess extending upward to the liver; pelvis also full of pus. Appendix retrocecal and adherent, four inches long; large perforation, gangrenous throughout, large concretions and free pus in lumen. Stump ligated and cauterized. Abscess, washed out with hydrogen peroxide and flushed freely with hot salt solution. Three cigarette drains; one to pelvis, one to under surface of liver and a third to appendical site. Convalescence uneventful, the usual moderate wound infection occurred, and healing by granulation. Discharged cured May 27, 1900. Thirty-five days.

Case VII. Gangrenous Appendicitis. Spreading Peritonitis.—Male, thirty-eight years old; admitted August 2, 1900. Sudden onset two days before, with pain and vomiting. Next day pain general, and more severe. Temperature said to have been normal. Examination. Patient enormously fat, looked very ill; pain and tenderness over appendical region; some abdominal distention. Temperature, 102.4° F.; pulse, 100; respiration, 28.

Operation.—August 2, 10 P.M. Long oblique incision on account of fat abdominal wall. Foul smelling free pus on opening peritoneum, abscess cavity about appendix extended to brim of pelvis. The appendix lay to inner side of cecum, four inches long, and entirely gangrenous. Contents, foul pus and fecal concretions. Excised stump inverted by purse-string suture. Field disinfected with hydrogen peroxide and flushed with salt solution; cigarette drains. Convalescence uneventful, moderate wound infection, healing by granulation. Discharged August 30, 1900, with very small granulating wound. Twenty-seven days.

Case VIII. Gangrenous Appendicitis Abscess Spreading Peritonitis.—Female, aged twenty-five years; admitted January 24, 1901. First attack two years ago. Duration of present illness about eighteen hours. Acute onset. Examination. Slight rigidity and some general tenderness. Temperature, 99.4° F.; pulse, 106.

Operation.—Jan. 25, 1901; McBurney incision, abscess opened and about two ounces of foul-smelling pus evacuated. Abscess cavity washed out with hydrogen peroxide and saline, the appendix removed, and its stump inverted by Lembert sutures. The pelvis also contained a large quantity of free pus. This was washed out with saline and a small drainage wick was introduced, also one to the appendical site. Appendix three inches long; gangrenous at its distal end and perforated. Wound closed to drain, which was removed in about thirty-six hours, and patient discharged cured Feb. 24, 1901. Thirty days.

Case IX. Acute Appendicitis. Spreading Peritonitis.—Male, eighteen years old; admitted March 5, 1901. Acute seizure same day. Patient looked very ill, some general and marked local tenderness, no tumor. Temperature, 104° F.; pulse, 100; respiration, 28. Second attack. Immediate operation 10:30 P.M.

Operation.—McBurney incision, free seropus escaped on opening the peritoneum and the pelvis and lower abdomen found to contain a considerable quantity of the same. Appendix removed and stump invaginated by a purse-string suture. Peritoneal cavity flushed with hot saline solution. Wick drain to pelvis and one to appendical site. Appendix four inches long, stricture at proximal one-third perforation at point distal to this with feces escaping. Section reveals mucosa showing spots of superficial ulceration and a gangrenous area involving the whole thickness of wall at point of perforation. Wicks removed in thirty-six hours; usual wound infection occurred; convalescence uneventful. Discharged as cured April 2, 1901. Twenty-seven days.

Case X. Perforated Appendicitis. Spreading Peritonitis.—Male, aged five years; admitted March 15, 1901. First attack, acute seizure, twenty-four hours' duration. Examination. Slight distention, some rigidity, tenderness general, but more marked in the left iliac region. Temperature, 101° F.; pulse, 120; respiration 40. Looked very sick, removed at once to the hospital and operated upon at 9:30 P.M., same day of admission.

Operation.—McBurney incision, free seropus in peritoneal cavity. Appendix four inches long, and extending nearly horizontally across the abdomen and with its free end to the left of median line. Perforation one-half inch from tip, excised and stump invaginated by purse-string suture. Peritoneal cavity from beneath the liver to the pelvis flushed with hot saline solution and the wound closed to a small wick drain extending to the bottom of the pelvis. There were small flecks of fibrin on the intestines, but no limiting adhesions, while seropus was pretty well distributed through lower abdominal cavity. The distention yielded to saline cathartics and enemata and the recovery was uneventful, moderate external wound infection. Healing by granulation, discharged as cured April 5, 1901. Twenty-one days.

Case XI. Acute Non-perforative Appendicitis. Spreading Peritonitis.—Male, aged forty-one years; admitted March 30, 1901. Abdominal discomfort for past six weeks, acute seizure thirty-six hours' duration. Examination.—Rigidity, general tenderness, slight distention, no distinct tumor. Temperature, 102° F.; pulse, 134; respiration, 32.

Operation.—March 31, 1901. McBurney incision enlarged by extension through posterior rectus sheath. Free pus in peritoneal cavity; intestines congested and somewhat distended. Cecum very movable and entirely covered by peritoneum. Appendix to inner side, sharply angulated in the middle, and extending nearly over to the middle line; 4½ inches long, congested and filled with soft feces. Mucosa echymotic, no ulceration, or perforation. April 1,

wick removed; April 10, wound healed; April 14, discharged cured. Fifteen days.

Case XII. Gangrenous Appendicitis. Spreading Peritonitis.—Female, aged eleven years; admitted January 20, 1902. Forty-eight hours' duration, acute sudden onset. Examination.—Marked tenderness, no tumor. Temperature, 102° F.; pulse, 100; respiration, 25. Looked very ill.

Operation, same day. Oblique incision 3½ inches long, through muscles. Free pus in peritoneum, creamy, foul-smelling and thick. Appendix nearly four inches long, extending to pelvis; gangrenous area with small perforation. Excised and stump invaginated, two wick drains. Some pain and distention after operation, required frequent enemata. External wound infected but rapidly cleaned up. Patient discharged as cured February 23, 1902. Thirty-four days.

Case XIII. Gangrenous Appendicitis. Spreading Peritonitis.—Male, aged twenty years; admitted February 15, 1902. First attack, fourth day, acute onset, very tender, good-sized mass. Temperature, 102.4° F.; pulse, 110; respiration, 24.

Operation same day. Oblique incision, large abscess evacuated and the appendix, the distal end of which was gangrenous but not perforated, was removed and the stump invaginated in the usual manner, after the usual washing with hydrogen peroxide, followed by saline. The pelvic cavity contained a large amount of pus and considerable free seropurulent fluid was present in the lower abdomen and a few strings of recent fibrin on intestines. Peritoneal cavity and pelvis flushed with hot saline solution. Peritoneum closed to two small wick drains extending to pelvis and appendical site. External wounds partially closed. Patient in bad condition, saline infusion and free stimulation required. Feb. 17, still vomiting, but condition materially improved, drains removed; Feb. 18, delirious all night; April 24, in typhoid state, wound foul; Widal test, negative. March 2, wound cleaned, much improved; March 12, sitting up; March 16, discharged cured. Twenty-nine days.

Case XIV. Gangrenous Appendicitis. Spreading Peritonitis.—Female, aged twenty-seven years; admitted March 8, 1902. First attack, acute onset, previous morning. Some distention, fairly rigid, more or less general tenderness; no distinct tumor. Temperature, 101° F.; pulse, 120.

Operation same day. McBurney incision. General peritoneal cavity full of thin, turbid, greenish-yellow fluid, large flakes of fibrin. Appendix removed, stump invaginated and wick drain inserted to site. The appendix was gangrenous and perforated. After flushing the peritoneal cavity with salt solution and suturing the abdominal wound, the stomach was washed out, and one ounce of saturated solution of Epsom salts was introduced through the stomach tube. March 9, wick withdrawn. Bowels moved and patient doing well. Moderate wound infection, healing by granulation; wound clean by March 20 and strapped. Discharged as cured March 21, 1902. Thirteen days.

Case XV. Gangrenous Appendicitis. Spreading Peritonitis.—Male, aged eleven years; admitted March 15, 1902. First attack, acute; sudden seizure that morning; frequent vomiting. General tenderness, both recti tense, especially the right, no tumor. Temperature, 101.8° F.; pulse, 140; respiration, 40.

Operation same day. McBurney incision. Large amount of free yellowish, turbid fluid in the abdominal cavity. Appendix short, swollen and its distal third gangrenous and perforated. Wick drain, partial closure of wound. Usual after-treatment. Wound healed by granulation, out of bed March 29. Discharged cured April 7, 1902. Twenty-three days.

PRIMARY MYOKYMIA; WITH REPORT OF A CASE.[1]

BY ROBERT M. DALEY, M.D.,
OF NEW YORK;
CLINICAL ASSISTANT, DEPARTMENT OF NEUROLOGY, CORNELL UNIVERSITY MEDICAL COLLEGE.

MYOKYMIA is a disorder characterized by fibrillary and wave-like contractions of the individual fibers of various muscles of the body without locomotor effect. It is more than a simple fibrillary tremor, for the whole body of the muscle also undergoes rather slow wave-like contractions passing from one end to the other. The condition rarely occurs primarily. Usually it appears as a minor symptom; in diseases of toxic origin, such as lead and mercurial poisoning, etc., and after attacks of poliomyelitis. It is also seen in neurasthenia and in sciatica; and in diseases characterized by rapid bodily wasting. It may occur as in my case as the only morbid condition.

Myokymia is one of those types of spasm closely allied to and often identical with cases reported as paramyoclonus. Dana regards Friedreich's case of paramyoclonus multiplex as really belonging to this group. That it may exist in conjunction with a myoclonus is shown by Kny, who first reported this condition in 1888, under the term of *paramyoclonus fibrillaris multiplex.* Later, Schultz, in reporting a true case, gave it the name of *myokymie.* Giovanni Biancone gives the name *myokymie* to a special group of cases of myoclonus characterized by fibrillary contractions of the muscles, in which those of the face may participate. He states that in these cases, the electrical excitability of the muscles involved is sometimes increased, and there is always an unduly persistent contraction after the excitation has been discontinued. Paresthesia and paralgesia form part of the clinical picture of the group. According to Bastianelli, only five such cases are on record,—his own, Biancone's and others by King and Schultz.

This case which I am reporting would come within the group described by Biancone. Later cases reported by Williamson, Walton and Dana,

[1] Received for publication Feb. 13, 1904.

bring up to thirteen, the number of cases in which myokymia is reported as the primary, dominant and most annoying symptom.

George P., aged twenty-eight years, single, native American, white, printer for fourteen years.

Family History.—The patient is one of five children; two brothers died in infancy; one uncle (mother's side) died of consumption, one cousin (also maternal) had chorea or epilepsy. Family history otherwise negative.

Previous History.—The patient does not remember having had any of the diseases of childhood, save mumps, which he had one year ago. Has had a moderate catarrh of nose and throat all his life. Suffered from fever and ague off and on, for two years, twelve years ago. No history of lead colic. Has always been interested in athletic exercises and pursued them to excess. Six years ago he rode the bicycle to excess. During two years he made 150 century runs, besides usual riding; also did cross-country running and played basket ball at night after work. Ten years ago, after taking part in a political parade, his legs pained him and he felt very tired. He has always been a great walker. He has never drunk to excess and never averages more than two drinks a week. Smokes a pipe considerably. Denies venereal diseases or excesses.

Present Illness.—About a year ago, after walking for eleven hours steadily, he noticed that the muscles in the calves of his legs twitched. This symptom has increased, and continued ever since. He both sees and feels the muscular twitching, and at night he can feel the sides of the face next to the pillow twitch. His forehead feels itchy at times. His legs seem heavy after walking a short distance, and also pain him. At times there are itchy or prickly feelings in them. His arms also get tired after moderate exertion. He states that his memory is not so good as formerly,—as he will forget to do things his superior tells him. He stands all day at his work. Otherwise, he feels well; there is no headache, no pain anywhere else. The appetite is good, the bowels regular. He has been in the country the past summer for a couple of months, and during this time has gained fourteen pounds.

Physical Examination.—Of rather slight build, but well nourished, figure regular. No anatomical stigmata of degeneration. Has some pes planus. Lungs negative. Heart normal in size and action; there is a faint mitral systolic murmur transmitted only to the anterior axillary line. Pulse normal frequency, no arterial thickening. There is no evidence of congestion in feet and hands. Liver and spleen apparently normal. Urinary examination shows few crystals uric acid, otherwise normal. Thyroid small.

Examination of Nervous System.—Gait and station normal. There is no paralysis or paresis of muscles. Facial innervation more marked on right side. Moderate tremor of hands. There is a fibrillary twitching of all the muscles of the legs and the posterior muscles of the thigh. The adductors and the quadriceps are not involved. This phenomenon consists of a constantly recurring contraction of muscular bundles, sometimes the same bundle contracting once, more often several times. The distribution of the muscles affected is symmetrical. These fibrillary contractions occur in every visible portion of the muscle, and evidently take place throughout the entire muscle substance. They involve sometimes a small bundle of the muscle, and sometimes a larger one. I have never seen the contraction of a bundle wider than half an inch, but I have noticed the contraction of a narrow bundle running through the entire length of the gastrocnemius. Contractions may occur in different parts of the muscle at the same time. The rapidity of the contractions varies considerably; occasionally they are slow and worm-like—other times sharp and quick. The strength varies likewise. The movements are more marked when the muscle is in an active state, for instance when the patient is standing. He is conscious of these contractions and this constitutes his reason for coming for treatment.

A sharp blow on these muscles brings out a marked contraction of a bundle, often followed by several others. There is no atrophy. The electrical reactions are negative. There is no objective disturbance of sensation. Pupils large, react well to light, distance, ciliospinal and consensual. No limitation of field of vision. No disturbance of ocular motility. Fundus normal. No disturbance of smell, taste, or hearing. Superficial reflexes undisturbed. Deep reflexes—jaw-jerk increased, elbow and wrist normal. Knee-jerks increased; ankle-jerk normal. No clonus. No Babinski. The patient has been under observation for a year, during which time the contractions have persisted in the same manner as described, though now both quadriceps are involved, and the contractions are more frequent and more marked in the thigh muscles than before, the extent and character of the contraction in the calves remaining about the same. The size of the legs remains the same; the patient also states that he has noticed no diminution in their size since the onset.

The patient has been under increasing doses of strychnine, up to gr. $^1/_{15}$ t.i.d.; arsenic in increasing doses, up to ♏xv, t.i.d. Specific treatment, bromides, chloral, galvanism, exposure of spinal column to X-ray, conium, gelsemium and tonics—all with no beneficial effect, save that a combination of conium and gelsemium reduced the contractions to a marked degree for a time.

Of the cases previously reported, all save two have been among the laboring class, and these two had poliomyelitis in childhood and undoubtedly used the muscles not involved to excess in compensation for the weakness of the others—as in Walton's case it began in the unaffected muscles of the extremity which was affected by the poliomyelitis; in my case it was an athlete, and in two cases it followed or accompanied lead poisoning. In one it followed sciatica, and I have seen it in a case of sciatica not reported.

All these cases were males, ages running from

twenty-one to seventy-one years. In two of the cases the legs only were affected; in the remainder, the legs and arms or legs and entire muscular system, excepting in one instance, the hands, and in another, the face and neck. In Kny's case, as already stated, it was associated with myoclonus; in Dana's with myoclonus and myotonus. Painful cramps have appeared in some of the cases. None show atrophy of the muscles, or much disturbance of the general health.

Nearly all complain of general pains, indefinite in character, and also of becoming easily tired. Four cases were cured, and one improved by rest, galvanism, and warm baths. Of the pathology nothing is known. As I have said, nearly all the cases occurred among men who used their muscular system excessively. Acute congestions, poisons, or exhaustive hemorrhages also may produce results, varying according to the extent and duration of the morbid influence and the vitality of the nerve cells, from a myospasm to a poliomyelitis or an amyotrophic lateral sclerosis; from disturbance of the cell to its death. In this case, the excessive work put upon the spinal motor neurons has led to a chronic functional disturbance, shown by slight irregular discharges.

I believe the contractions are due, in this case, to a perversion of the normal efferent impulses, which are constantly passing to a muscle to preserve its normal tone, and that the cause of this perversion is due to some disturbance of the peripheral motor neuron. That it is not due to the nerves which conduct the afferent impulses from the muscle is shown by the fact that mechanical stimuli, which call for a contraction of the entire muscle, are responded to naturally, also other afferent impulses; the sensory vasomotor and trophic nerves are not disturbed. That there is no disturbance in the muscle itself, is shown by the lack of any nutritional change, and the fact that the entire muscle contracts naturally, both to electrical and voluntary movements. That this perversion is not due to a disturbance in the action of the sensory cells, but rather to the motor cells, is shown by the absence of any characteristic sensory symptom, and to the etiology which is one of the excessive use of the motor neuron.

This perversion is probably of a functional character, and due to a disturbance in the action of the cell.

The myoclonias or more or less generalized clonic spasms may be grouped as follows:

1. Peripheral myoclonus (including paramyoclonus of Friedreich, and fibrillary myoclonus of Kny) or myokymia.
2. Hysterical myoclonus (including some cases reported as paramyoclonus multiplex).
3. Cortical myoclonus, or convulsivetic.
4. Degenerative myoclonus or myoclonus-epilepsy or family myoclonus.
5. Chorea.

Groups 4 and 5 are closely related.

DIAGNOSIS AND TREATMENT OF INTERNAL HEMORRHOIDS.[1]

BY H. A. BRAV, M.D.,
OF PHILADELPHIA.

INTERNAL hemorrhoids may be defined as varicosities of the middle and superior hemorrhoidal veins, sometimes associated with eversion of the rectal mucous membrane. There is always more or less pain and tenderness with discomfort in sitting. Allingham describes three varieties of internal hemorrhoids: capillary, arterial and venous.

The capillary hemorrhoid is small, and is composed of the terminal branches of the arteries and veins and of the capillaries which join them. The capillary hemorrhoid never protrudes through the anus. It is covered by a delicate thin membrane and this accounts for the free bleeding which follows the slightest injury of its surface by the passage of hardened feces during the act of defecation. To this form of hemorrhoid the name bleeding piles may properly be applied. Some authors refer to this form of piles as the first stage of hemorrhoidal development.

An arterial hemorrhoid is of considerable size and consists of a tumor of freely anastomosing arteries which are tortuous and dilated and bound together by connective tissue. Such a tumor is firm to the touch and is liable to inflammation, erosion, hemorrhage and protrusion through the anal orifice during defecation, returning spontaneously into the bowel after the act has been completed.

This form of hemorrhoid is the result of repeated attacks of inflammation (irritation) of the capillary form of hemorrhoid which causes an increase in the submucous tissue. I shall refer to this form as the second stage of hemorrhoidal development.

The venous hemorrhoid consists of a mass of large dilated veins, beneath the mucous membrane of the rectum. Repeated irritation leads to hypertrophy and induration of the mucous membrane and submucous connective tissue and a large bluish tumor is formed, which protrudes during defecation or the protrusion may be continuous if the patient is not in the recumbent position. This stage is spoken of as the third stage of hemorrhoidal development.

The diagnosis of this most common and distressing malady is not difficult, although errors in diagnosis are of more frequent occurrence than is generally supposed by physicians who do little

[1] Read before the North Branch of the Philadelphia County Medal Society, January 13, 1904.

rectal work. Internal hemorrhoids are likely to be confounded with cancer of the rectum, polypus and prolapse of the rectum, because these conditions are likewise accompanied by hemorrhage, pain, protrusion at the anus and a discharge of mucus.

Errors are particularly liable to occur in diagnosing the disease, as met with in children because prolapse and polypus of the rectum are not uncommon affections in children and these diseases present some resemblance to internal hemorrhoids. It is true that internal hemorrhoids is a very rare affection in childhood, but cases have been reported by Allingham, Ball and others. My own experience has been limited to two cases occurring in children whose ages were five and nine years respectively.

The symptoms of a prolapsed and congested polypus are very similar to those of internal piles, consisting of a protrusion at the anus and occasional bleeding at the act of defecation but a careful digital examination will disclose the presence of the pedicle to which the growth is attached. Prolapsus of the rectum is easily distinguished from piles by the characteristic appearance of a reddish-purple mass with its depressed central orifice and the annular fold of tissue around the whole anus. The differential diagnosis between malignant growth and hemorrhoidal tumors is an easy matter, as the hard nodules on the side of the rectal wall with its comparatively firm structure, and surrounding induration can readily be detected on a digital exploration. The following cases, selected from a number of those which I saw confused with internal piles, will demonstrate the fact that a wrong diagnosis is often made:

Case I.—In March, 1903, a woman aged seventy years consulted me for what she thought to be bleeding piles. Her history was as follows: In April, 1902, she had an attack of diarrhea associated with rectal hemorrhages during the act of defecation. She consulted her physician who diagnosed her case as internal piles and prescribed ointments to be used locally, and internally some medicine to check peristalsis. She did not improve under this treatment but grew worse every day. When I saw her she complained of a constant desire to evacuate her bowels, but when at stool she passed nothing except blood and mucus. She said, she felt as if her bowels were never unloaded, and the excessive straining caused a sharp pain in the rectum.

I placed the patient in the right lateral and semi-prone position and introduced my index finger into the rectum in search of the cause of her ailment. Sweeping the finger around the walls of the first three inches of the rectum, I found nothing to account for her symptoms. Introducing a speculum in order to see whether there were any erosions or ulcerated areas, which may give rise to this bleeding, I found the lower portion of the rectum very much congested but no lesions were visible. Not being satisfied with the result of my examination, I requested the patient to stand up and I examined her in the erect position. While the patient was straining as much as possible, I again introduced my finger to its full length when the tip of my finger came in contact with a malignant stricture about four inches above the anus.

Case II.—A boy, eleven years old, was referred to me by his physician for a rectal examination. The history obtained from the mother was as follows: For over two years the boy suffered with tenesmus, diarrhea and at times passed blood and mucus from the rectum. Occasionally a bright-red mass would protrude from the anus and cause pain. He was treated by a number of physicians for internal hemorrhoids but failed to get relief. A digital exploration of the rectum revealed the presence of a polypus.

From what has been said it is obvious that the importance of a correct diagnosis of internal hemorrhoids cannot be overestimated. In the second and third stage of hemorrhoidal disease, when the piles protrude through the anal orifice and when they either return spontaneously into the bowel after defecation or protrude constantly, a careful examination will readily disclose the nature of the trouble. The pile tumors can then not only be seen as a dark blue mass, but they can also be felt between the fingers as a circumscribed and distinct tumor, being partly hard and partly soft, with a strict contiguity between the piles and bowel.

The difficulty in diagnosis arises in the early stage of hemorrhoidal development when there is no external evidence of internal piles, and bleeding is the only symptom present. Also when hemorrhoids are complicated with a fissure or an ulcer of the rectum, the spasmodic contraction of the sphincters is so great that the piles are not prolapsed, though they may bleed freely with each action of the bowels.

In such cases an examination should be made immediately after the rectum has been emptied by an enema, when the bearing-down efforts and water causes the hemorrhoids to protrude, enabling us thereby to determine the number and size of the tumors we have to deal with.

In woman piles may be brought plainly into view by everting the anus with two fingers introduced into the vagina and pressing upon its posterior wall. An examination in a case of internal hemorrhoids should never be terminated at the evidence of hemorrhoidal tumors, for it often happens that higher up a stricture exists which manifests no other signs of its presence except the hemorrhoids.

In outlining a rational method of treatment for internal hemorrhoids, it is necessary to bear in mind the etiological factors and pathology underlying this condition. We must remember the effects of the various causes of piles, whether the result of pressure as in constipation, foreign bodies in the rectum, retroversion of uterus, pregnancy or whether it is caused by reason of straining during micturition as in enlarged prostate and stricture of the urethra.

All these conditions lead first to a varicose condition of the veins and impediment of the return flow of venous blood and later to an increase in the blood vessels and proliferation of connective tissue.[1]

The belief that permanent cures cannot be effected with palliative measures or local treatment is surely true in the third stage of hemorrhoidal development, when we have to deal with a firm, hard, fibrous tumor. This, however, is not true in the first and second stage of hemorrhoidal formation. Here palliative measures should always be tried, and when skilfully and scientifically executed, we will not only relieve or soothe the symptoms of the disease without curing it, but by the alleviation of the existing cause and the employment of palliative measures we render an operation quite unnecessary. The dictum calling for the removal of the cause before treatment ensues is equally applicable to this affection.

Internal hemorrhoids secondary to stricture of the urethra, enlarged prostate, vesical calculus, pregnancy or neoplasm will completely disappear when these affections are cured. Knowing that constipation is the most common cause of internal hemorrhoids, we should first direct our attention to this condition and attempt to secure at least one daily evacuation of the bowels. This can often be accomplished without medicine by a change from a sedentary habit to active outdoor life and the avoidance of everything which tends to produce constipation. The diet should be regulated by eliminating from it all substances which tend to constipate the patient's bowels.

Highly seasoned meats, rice, cheese and potatoes, alcoholic drinks and the excessive use of tobacco, should be strictly prohibited.

If the prophylactic and dietetic measures are not sufficient to obtain a daily evacuation of the bowels, we have to resort to medicinal or local treatment. Mild aperients in the form of a mineral water in the morning, or a dose of cascara at night in addition to gentle massage of the sphincters with the finger, will be found very effective. The injection of two ounces of olive oil at bedtime and its retention over night is extremely beneficial, not alone because it softens the feces and facilitates its expulsion, but because it also prevents hemorrhage. The softening of the feces prevents the cohesion of scybala which invariably causes engorgement of the hemorrhoidal veins and the surface of the pile is not abraded by the passage of a hard fecal mass during defecation.

In cases of obstinate constipation, saline cathartics are indicated: drastics, however, should not be used. Hemorrhage is most efficiently relieved by the use of astringents and cold. The best astringent in these cases is cold water. After each passage, the bowel should be injected with cold water. A suppository of ten grains of tannic acid is also very efficient. When the hemorrhage is profuse, every mechanical means should be exhausted in determining the exact location of the bleeding point.

With our modern method of distending and illuminating the rectum, the bleeding point should be located before any effort at packing the rectum or hemostatics are employed for checking the hemorrhage. When the hemorrhage is the result of a general oozing from the surface of the piles, a single application of nitric acid or carbolic acid will often stop it forever; cauterization may also be made with the Paquelin cautery point, which is still more reliable. The application of these chemical caustics is not painful, and the beneficial results obtained so satisfactory that a trial of this procedure in controlling hemorrhage from capillary oozing from small vessels is, I believe, worthy of consideration.

Hemorrhage from a spurting vessel on the surface of one pile can readily be stopped by the application of a silk ligature to the bleeding point. This can be done without an anesthetic. Following the application of the ligature, the bowels should be confined for three days, after which time a cathartic is given to secure a daily natural evacuation afterward.

The injection of a moderately strong solution of carbolic into the center of the pile, results in a hardening and diminution in the size of the hemorrhoid. This atrophy of the tumor is produced by the inflammatory induration following the injection and by the subsequent cutting off of the circulation to the tumor.

The solution I employ is one part of pure carbolic acid to two parts of glycerin and two parts of water. The amount I inject into the hemorrhoid ranges between five and ten drops, depending upon the size of the tumor. I inject two and sometimes three tumors at a time, but I think the novice does better by injecting only one at a sitting. The injection may be repeated after the lapse of one week. When the injection is properly and skilfully performed, there is very litte pain following it, and the results are very gratifying. There is a gradual decrease in the size of the tumor, and in a few weeks the prolapse disappears and with it the bleeding, pain and discomfort. By this method, under the head of the palliative treatment, I am satisfied that I obtained complete cures in over 30 cases.

I do not advocate this method in preference to the radical cure by operation, but I often resort to it when patients refuse the surgical operation. The practical advantages of this plan of treatment may be summed up as follows: The patient is not frightened by the use of a knife, it is painless when properly performed, and it does not detain the patient from business. I believe that with the proper antiseptic precautions there is no danger of sepsis, abscess formation or sloughing.

Regarding the permanency of the cure, it may be said that after the exciting cause is removed

[1] The treatment of internal hemorrhoids is generally considered under two heads: First, palliative; second, radical cure by operation. A large majority of sufferers from internal hemorrhoids will not submit to a radical cure in spite of the advantages and the safety and facility with which it may be accomplished.

In my experience, comprising both private and hospital practice, three out of five object to the use of the knife and general anesthetic. It is, therefore, of paramount importance to know what can be done for such patients without any surgical interference.

and the prophylactic measures are successfully carried out there may be no recurrence of the trouble. I have seen cases of recurrence following the clamp and cautery and the ligature operation if the preventive measures have not been adhered to. Piles should not be injected when highly inflamed, when external, strangulated or when ulcerated. We may at any time be called upon to treat a case of strangulated piles and the condition is an extremely painful one. We usually find a mass of piles, swollen, congested and edematous which are tightly constricted by the external sphincter. The pain is so severe that a large majority of patients will readily submit to an operation, which should be performed at once. If an operation is refused, lead-water and laudanum lotion applied ice-cold, affords great relief, and so reduces the edematous swelling that the piles may be replaced. Their reduction by taxis requires much care and judgment. After anointing the mass with vaseline one finger is gently introduced into the anus and the other fingers press the tumors one by one within the bowel. This, if possible, should be done under the influence of an anesthetic, for the maneuver is a very painful one and the reduction is sometimes impossible without an anesthetic. Under the use of cold and sedative applications and rest, the condition will subside in forty-eight hours, when the patient is able to effect a reduction himself.

The operative treatment is the safest, as it does not require much time to bring about a radical cure. It is the intention of the writer to only refer briefly to some of the numerous methods of operation for internal hemorrhoids. Of all the various operative procedures I prefer the ligature or Salmon's operation. This operation can be performed in a short time and is accompanied by very little bleeding. There is no risk of hemorrhage if the ligature has been tied tightly and the loss of healthy mucous membrane can more easily be prevented by including only the pile in the ligature. And the period of convalescence is short, as a rule from two to three weeks. If the operation has been properly performed there will be no recurrence of the piles. This operation can be performed with fewer assistants than any other operation adopted for the operative cure of hemorrhoids. I will not weary you with a detail description of the various steps followed in applying the ligature as the procedure is known to all of us. I only wish to state that I do not cut off the pile after the ligature is tied unless a pile happens to be very large. After the piles are tied, I replace them within the bowel. I finally insert into the rectum a firm piece of rubber tubing 3½ inches long and an inch in diameter, around which sterile absorbent cotton is wrapped. This is kept in place by placing a safety-pin through the outer end and into a T-bandage. This tube serves three purposes: First it allows the escape of flatus, which is the chief cause of the discomfort after the operation; second, through this tube possible bleeding can be detected; third, if after the third day a cathartic is administered and no action of the bowels is obtained, an enema can be given through the same tube. Immediately after recovery from the effects of the anesthetic, a powder composed of one-fourth grain of morphine and ten grains of bismuth should be administered every four hours for two days in succession. This is necessary to keep the bowels confined for about four days, at the end of which period they should be relieved by the administration of a laxative and, if necessary, an enema. The external dressing should be removed twenty-four hours after the operation and a fresh dressing should be put on every night and morning until the wounds are healed. The ligatures will ordinarily slough off in from eight to ten days. When this operation is properly performed there will be no considerable suffering following it, surely no more than after the clamp and cautery operation.

There is one other operation which has won for itself a very enviable reputation, and, I think, is the best after the ligature operation, and that is the operation by clamp and cautery or Henry Smith's procedure. Some surgeons claim that this operation is not followed by pain if care has been taken to avoid cauterizing the skin. I cannot agree with them, for I saw marked pain after it. The edema of the mucocutaneous tissues following this operation is very great.

Some time ago while demonstrating such a case to a number of physicians, I was asked why I did not remove all the piles, as they thought the edematous mass around the anus were piles. Such a condition is the cause of considerable suffering, and while this is not present in every case it occurs frequently enough to warrant the statement that this operation is just as often followed by pain as the ligature operation. It is furthermore claimed by the advocates of the cautery operation that the patients can be about in a few days and that they are not detained from business more than a week. I do not find this a safe procedure, because the wounds are not entirely healed by that time and the irritation produced by walking or straining while at work will lead to increased granulation and subsequently to the formation of a stricture. I have seen a number of such cases in patients who were permitted to attend to business one week after the operation, returning about four or five weeks later with marked stenosis. It is advisable to keep the patient under observation for three weeks, during which time he should not be permitted to exert himself in the least. The patient may be up and about in the room after a week or ten days, but should be in the recumbent position the greater part of the day.

I have already indicated my preference for the ligature operation and only wish to add that this treatment requires skilful supervision in order to be successful. But when successfully carried out it has yielded, in my observation, more satisfactory results than any other operation.

My experience in the treatment of internal hemorrhoids lead me to arrive to the following conclusions:

1. In the treatment it is important, in the first

place, to determine whether the disease is primary or secondary to some affection of the pelvic organs.

2. In the first stage of hemorrhoidal disease no operative treatment is indicated.

3. The true value of the non-operative treatment is frequently underestimated in the second stage of hemorrhoidal disease.

4. None but operative treatment should be resorted to in the third stage of hemorrhoidal disease.

OBSERVATIONS ON OBSTETRICS IN GENERAL PRACTICE.[1]

BY J. F. MCNULTY, M.D.,
OF CALLAWAY, NEB.

THE art of assisting women in childbirth in general country practice differs but little from the same function in private city practice.

The general practitioner is working at a disadvantage, as he is frequently called without a moment's notice, while the specialist has generally a line on his case during the whole period of gestation. The general practitioner is very frequently brought face to face with serious and alarming situations without notice, and quite often without sufficient preparation. The ability to cope successfully with what may be called emergency cases requires a cool head and rapid judgment. The physician must have the faculty of doing nothing at the wrong time, and the ability to act promptly at the right time.

We should constantly keep in mind the fact that meddlesome midwifery is poor midwifery. We are called simply because it may become necessary to assist nature in the expulsion of the products of conception, but with the distinct understanding and hope that our efforts will not be required.

1. We may become meddlesome by rupturing the membranes too soon. Show me a man who has a record for using the forceps, who, in fact, is forced to use them often, and I will show you a man who is a chronic premature rupturer of the amniotic sac. No branch of medical practice furnishes such positive evidence regarding the germ theory of disease.

2. We can become, and unfortunately do become, meddlesome, by introducing diseased germs into a very fine culture medium—the contents of the human uterus. By cleanliness and the strict attention to the details of antiseptic surgery much trouble may be avoided. I now have a case of puerperal fever, where the attending physician neglected to prescribe even a carbolic acid wash.

The attending physician should prepare as for a surgical operation in every instance. There should be no situation which would call for a hasty examination without first giving marked attention to the preparation of your hands. The obstetrical practitioner of to-day should always remember that he is, for the time being at least, a surgeon, when called upon to use any kind of instrument.

3. We can, and do, become meddlesome by neglect. Neglect to repair a laceration immediately. The gynecologists grow rich upon the neglect of the obstetrical practitioner. Nine women out of ten who consult for private trouble date their period of suffering from a particular confinement or a particular miscarriage. You have in a laceration a fresh wound. Sew it up; dress it surgically, and no trouble follows. If not sufficiently large to require a ligature, merely apply an antiseptic dressing instead of allowing it to ulcerate and become an avenue of infection.

Few persons die during an operation; few women die during delivery; but the effects resulting from operations and deliveries give us deaths by the thousands. Suppose the case of puerperal fever of which I spoke should die, or should recover and later develop pus tubes, and the removal of them should cause death, where should the primary cause of death be placed?

Neglected abrasions of the vaginal mucous membrane, slight lacerations of the cervix with more or less tearing of the pelvic floor, are, I believe, the primary causes of the major portion of female complaints.

We should see that the various organs after delivery are placed in the position which nature intended them to occupy. More tissue should be placed to support the uterus than just sufficient to afford covering for the contents of the rectum. We must answer for a great many prolapses, not because of what we have done, but of what we have left undone.

My old professor, Dr. Earl, of the College of Physicians and Surgeons, Chicago, was in the habit of saying: "Remember, boys, you cannot prevent a child from being born." The child will be born, as a rule, in spite of us, but it is very essential that we have at our finger tips the normal diameters of the pelvis and the fetal head; also the positions the fetal head may assume in passing through the parturient canal. These points are called the alphabet of obstetrics, and every physician should have a mental picture of the situation, no matter what position the child's head may be forced to assume. The ability to follow the fetal head properly and accurately comes only by painstaking observation.

How few of us endeavor to make out the various positions and mentally review the diameters while attending a case! I think it good practice to go over this old alphabet in every instance, no matter how normal it may be. Then when we come in contact with an abnormal situation, we at once recognize it, and can prepare to meet it promptly. If we find that natural efforts are not sufficient to meet the new conditions, and artificial aid is absolutely called for, then act without delay—giving ample time for thorough preparation, however.

Offer no excuse for using forceps. When indicated use them just as you would a certain drug if indicated in a given case. I was recently

[1] Read before the Custer County Medical Society, Broken Bow, Nebraska, February 9, 1904.

obliged to use forceps in a case where the membranes had ruptured two days previous to the beginning of actual labor pains. The mother was a large, healthy and strong woman, twenty-eight years of age, this being her second child. The occiput was found to be in the left posterior position. It failed to make the turn, and remained fixed. The patient became exhausted, and the natural efforts were such that it was evident artificial aid would be absolutely required. After thorough preparation the patient was chloroformed, forceps were placed in position, and the child delivered. By removing the forceps before the fetal head has passed over the perineum we avoid the lacerations which sometimes occur when delivery takes place with the forceps in position. I believe it is not good practice to endeavor to rotate the head of fetus with forceps in position, although we are at times advised to do so.

Upon making the usual call the next day I found patient to have a degree of fever. I frequently find a slight fever on second or third day, to which I pay no attention. There is a decided difference between the fever of sepsis and that of exhaustion or reaction. We may do harm by ordering vaginal injections in such cases. However, when the discharge is offensive, with fever or without, I invariably use vaginal douches. If no rapid and decided improvement takes place, irrigate the uterus, and in every case inspect cervix and vagina.

There is no class of cases where symptoms vary more widely than in premature deliveries, although the cause is the same in each. If, in such cases, I find the os dilated, pain and hemorrhage, the prospect of saving the child is poor indeed.

Driving, as we do, many miles in the country to see such patients, I have made it a practice to dilate rapidly, if necessary, and turn out the entire contents of the uterus. The prospect of hemorrhage following a complete operation of this character is slight. The danger in those cases comes from leaving some of the after-birth intact. Here, again, the trust-to-luck obstetrician is apt to have a sudden or remote death on his conscience.

It is very essential that we manage breech presentations with great caution. Until the breech appears in the vulva there is, as a rule, no danger to the child. But we must act quickly when the breech appears.

If we have hastened labor by force, there is the danger of the head approaching the brim of the pelvis before dilatation is fully established. If dilatation is not fully established, then the labor will be most difficult. Force and haste on our part, when neither are called for, is the great difficulty in those cases. The temptation is great. Avoid it. The lower uterine segment offers the obstruction in a large majority of those cases when we are inclined to attribute the cause to a contracted pelvis.

Deliver both upper extremities with the body of child. Place forearm under the body, and fingers in child's mouth and make traction on breech. Force should be exerted toward the pelvis of child to avoid fracture of the femur. I have never been obliged to place forceps on breech to aid delivery.

Let us shortly consider a few diseases that influence the course of pregnancy. Abortion and premature labor may be caused by an attack of pneumonia. Pneumonia, during the last few months of pregnancy, is especially to be dreaded, as fully one-half the cases die. Hence our prognosis should be grave. If the mother, in such a case, is threatened with asphyxia, we are justified in causing premature delivery.

Pleurisy may cause premature delivery, but the course is not influenced by pregnancy to any great extent.

The tubercle of consumption will, if the general condition of the patient is good, remain in a latent state during pregnancy, but when the patient is debilitated the disease generally breaks out with renewed vigor. Such persons should not be permitted to nurse the child.

Auto-intoxication arises from sluggish action of the kidneys and liver. The earlier in pregnancy the lesion of the kidneys manifest itself, the more serious for both mother and child.

I am in the habit of sitting by the bedside in every instance and occasionally kneading the uterus—to insure contraction—for one full hour after the delivery of the placenta. Never leave the house while the woman has a pulse of over one hundred. When we feel hard, firm contraction, with a steady pulse and a temperature below one hundred, we may turn to our couch and sleep the sleep of sometimes profound exhaustion.

MEDICAL PROGRESS.

SURGERY.

Cervical Zones of Hyperalgesia after Cerebral Injuries.—It is an accepted fact that where areas of the skin present certain sensory disturbances, the cause of the latter may be found in some lesion in an internal organ. R. MILNER (*Berl. klin. Woch.*, April 25, 1904) believes that with some modifications this principle may also be applied to injuries of the head. He reports a case where, after the infliction of a bullet wound which involved the surface of the brain, but did not lead to any marked general symptoms, localized areas of analgesia could be mapped out in the neck. In this instance there was probably a direct irritation of the minute divisions of the sympathetic, either in the pia or in the gray matter, and the extent of the hyperalgesic zone corresponded to one of the upper cervical segment, probably the second. The author thinks that further study of these zones may be helpful in the diagnosis of cerebral injuries, especially when the picture afforded by the X-rays is not sufficiently clear or conclusive.

New Method for Exposing the Liver.—A novel operative procedure for reaching the posterior surface of the right lobe of the liver has been suggested by J. ISRAEL (*Deut. med. Woch.*, March 31, 1904). The patient which he reports was believed to have a tuberculous right kidney. There was pain on pressure in the lumbal region, which was believed to be due to the kidney. The latter was exposed from behind after resect-

ing the twelfth rib and then pushed to one side after being freed from its attachments. The posterior aspect of the right lobe of the liver was thus exposed and on it was seen a tumor, which was removed. It proved to be a gumma and the patient made a good recovery under appropriate treatment. Although there may have been some doubt as to the propriety of surgical intervention in this case, still the advantage of reaching this region of the liver was shown. It is indispensable however, that the pedicle of the kidney is sufficiently long to permit pushing the kidney to one side.

Appendicular Inflammation.—An important fact to bear in mind, that so long as the mucous membrane is intact there can be no infection of the appendix from within. This layer also contains numerous large lymph follicles, which later may extend throughout the next two deep layers. To these lymph follicles, LOUIS FRANK (*Am. Jour, of Obst.*, March, 1904) attaches great importance. In numbers they vary. At the base of the lymphoid follicle, which is analogous to the solitary follicle in the large gut, there is an opening between it and the surrounding structures. This is the basal lymph sinus of Clado. Sometimes these follicles open directly upon the mucosa. The lymphatics of the appendix enter the mesoappendix, where some of them pass through a lymphatic gland, situated at the ileocecal angle. From the mesoappendix enter the mesentery and then pass onward. The lymphatics also communicate directly with those in the iliac fossa, along the course of the external iliac artery. The classification of catarrhal, suppurative, gangrenous perforative, etc., is all wrong from a pathological standpoint. It is not possible, even clinically, to always recognize the changes taking place in the organ, so it is better to speak of all cases as merely an inflammation of the appendix with suppuration, with rupture, with abscess, etc. This conveys a correct clinical or pathological idea of the condition laid before us. In all cases, whether the cause operate from without, as from embolus, hernia, etc., the one and sole cause of inflammation itself in the appendix is bacterial invasion. Without this there is no pus or inflammation, or even death, no matter what may be the interference with the blood supply. For bacterial invasion, loss of epithelium or greatly lessening of its vitality is necessary, and this is found to be true in all cases examined. Having once entered the lymph channels the organ is doomed, and though it may have been years since the bacterial entrance, they will be found upon examination, unless the inflammation has resulted in obliteration. The essential factor in all inflammation is bacteria, and no matter how active the predisposing factors may be, how extensive or severe the torsion of an organ may be, or how large the embolus present, so long as microorganisms are excluded, no peritonitis will be found.

Removal of One-half Thyroid Gland.—The main difficulties in operations on the thyroid gland are: (1) Hemorrhage; (2) injury to the recurrent laryngeal nerve; and (3) expression of the contents of the gland by manipulation of the organ during operation. To avoid, so far as possible, these difficulties, J. G. SHELDON (*Med. Rec.*, April 9, 1904) employs a method which was previously used by A. P. Gould. After the gland has been exposed by either a transverse or angular incision, a Kocher's director is passed between the isthmus and the trachea. A stomach clamp is then placed upon the isthmus close to the lobe which is to be left, and another clamp close to the first upon the isthmus. The isthmus is then cut between the clamps and with the lobe to be removed is turned outward. The under surface of the gland is then separated from the underlying tissues with the finger covered by gauze. The arteries are thus easily seen and clamped, the inferior one generally first and the recurrent laryngeal nerve is usually easily found beside the inferior thyroid artery. After the arteries have been tied the veins do not bleed, and as it is very difficult to tie the arteries without previously cutting several veins where the gland is attached from in front and to the outer side, a great advantage is thus gained by the method described. Furthermore, when the enlargement of the lobe is of considerable size it is always external to the point where the superior artery enters it and hence the operation must necessarily be more or less bloody before the artery can be reached. The manipulation of the gland is also much less injurious when done by this method and the dangers of toxemia are diminished. Tubular drainage should always be used for ten to twelve hours on account of the profuse primary wound secretion and the danger that some of the gland contents may have been expressed.

MEDICINE.

The Blood Examination in Abdominal and Pelvic Diseases.—During the past two years the value of the blood estimation in abdominal inflammations has received much attention by surgeons. In a critical review of the literature for this period, E. SCOTT CARMICHAEL (*Brit. Jour, of Obstet.*, Feb., 1904) finds that the various writers upon this subject have come to the following conclusions: The red blood corpuscles and the percentage of hemoglobin afford but little help in diagnosis, although in acute toxemias the amount of both is very considerably diminished. Their diminution, along with a slight leucocytosis according to Bender, is a sign of malignancy in tumors. A leucocytosis is undoubtedly more reliable than the temperature in the diagnosis of pus, especially in the more chronic cases. The tendency to look upon a certain definite number of leucocytes as indicative of pus must be avoided. In general there is not such a high degree of leucocytosis in purulent inflammations of the female genital organs as there is in such conditions of liver abscess and suppurative appendicitis. The more chronic the inflammation the lower the leucocytosis, so that a lower count in chronic inflammations must be regarded with suspicion. In gynecology it forms a most valuable aid to the differential diagnosis of tubal conditions, and is often of great value in determining the advisability of an abdominal or vaginal operation. The leucocyte count should be made at regular intervals and compared with the temperature curve. After operation the leucocyte count may indicate the completeness or otherwise of drainage in suppurating cases. The relative value of the quantitative and qualitative count is open to opinion. For the clinician the quantitative count is easily performed, and is sufficient in the majority of cases. The value of the qualitative count is diminished in value by the fact that much experience is required for the enumeration, which cannot be easily gained by the ordinary clinician. In the hands of the laboratory expert, it is probably of more value than the quantitative count for diagnostic purposes. The same may be said of the idiophilic reaction.

Hypoleucocytosis in Typhoid.—The great value from a diagnostic point of a hyperleucocytosis is known to all, but in one disease at least the opposite condition, hypoleucocytosis, plays an equally prominent part. In 53 mild cases of typhoid, L. KAST and C. GUTIG (*Deut. Arch. f. klin. Med.*, Vol. 80, Nos. 1 and 2), found the leucocytes below 7,000 in 47, between 7,000 and 9,000 in four and above 9,000 in two. For 31 severe cases the figures were 30, 1 and 0 respectively, and for 21 fatal cases 20, 1 and 0. Even the presence of complications caused by germs other than the Eberth bacillus is not likely to increase the number of white cells; thus for

25 cases the majority of which also suffered from staphylococcus infection, the figures were 20, 3 and 2. They inculded cases of severe bronchitis, lobar and lobular pneumonia, decubitus, icterus, colpitis, etc. A constant leucocytosis is generally found only after hemorrhage so that no conclusions should be drawn in doubtful cases if an intestinal bleeding has occurred recently. Prognostically, relatively high counts seem to speak for a favorable outcome ,if observed repeatedly, while a sudden decrease of lymphocytes is an ominous sign. Diagnostically, above 12,000 almost certainly rules out typhoid, while below 7,000 and more so, below 5,000, makes typhoid exceedingly probable. Other peculiarities of the blood are a tendency of the neutrophiles to diminish, an absence of acidophiles and a slight decrease of lymphocytes up to the third stage when the latter begin to increase. Non-typhoid complications generally cause a slight, relative polynuclear increase which does not alter the leucopenia. The value of the various diagnostic aids in typhoid may be set down as follows: Widal 95 per cent., hypoleucocytosis 90 per cent., splenic tumor 86.6 per cent., diazo 75-85 per cent., roseola 69 per cent., while for the early diagnosis the order is as follows: Hypoleucocytosis, Widal, roseola, diazo and splenic tumor. The latter three are of about equal value. That hypoleucocytosis is of more value than the Widal in the first stage is evident from the author's cases where the latter was negative in about 13 per cent. Hypoleucocytosis may also occur in the following conditions: Inanition, measles, Banti's disease, severe secondary or essential anemia, malaria, pulmonary tuberculosis, tuberculous meningitis, acute miliary tuberculosis, sepsis and severe pneumonia. In many other conditions, the leucocytosis is first preceded by a diminished number, but this leucopenia is only relative since an accumulation of leucocytes occurs in the internal organs at the expense of the peripheral circulation. Diagnostic difficulties are only liable to arise with malaria (here the presence of plasmodia, of basophile punctuation and pathological changes in the shape of the erythrocytes, the normal or increased number of acidophiles and the occurrence of melanin in the leucocytes will aid), tuberculous meningitis, acute miliary tuberculosis, sepsis and severe pneumonia. In paratyphoid the blood composition seems to be the same as in typhoid.

Deficient Urea Excretion in Gout and Lithemia.—The diminished urea excretion which has been frequently noted in chronic gouty subjects has been generally attributed to the co-existing nephritis. R. K. MACALESTER (*Med. Rec.*, April 16, 1904) has made repeated examinations in some 20 cases of gout and lithemia unaccompanied by any demonstrable nephritic conditions and has invariably found that there is marked deficiency in the urea and uric acid excretion in these cases. This diminution is not present in chronic rheumatism and this fact, he claims, makes it easy by laboratory means to diagnose one condition from the other. The total urea output in gout, he finds, is considerably lower than that found in chronic Bright's disease, about two-thirds the amount excreted in other miscellaneous chronic disorders and about three-fifths the quantity excreted in health. He believes that it points to a defective hepatic metabolism, there being no clinical evidence of kidney trouble in support of the renal theory. Gout, goutiness and lithemia are thought to be of the same origin, but modifications of the same disorder and are, in general, more amenable to treatment, especially to balneotherapy than chronic rheumatic affections.

Accuracy in Measuring Blood-Pressure.—In order to determine accurately when the pulse disappears and reappears with the Riva-Rocci apparatus, G. GROEDEL and F. KISCH (*Münch. med. Woch.*, April 19, 1904) have resorted to special apparatus which records the pulse-curve graphically. They find, however, that almost the same results are obtained with the palpating finger. With long-continued experiments the sense of touch may be blunted, but the eye may also fail to record the almost microscopical excursions of the accessory instruments. The rudimentary pulse-curves recorded upon the apparatus can generally be felt with the finger as well.

Influence of Cold on Heart Action.—It is quite universally believed that cold acts as a sedative to cardiac action. Some careful observations have been made on this point by W. KREBS (*Berl. klin Woch.*, April 25, 1904) in a number of patients presenting various diseased conditions. He comes to the conclusion that a certain class of patients suffering from cardiac insufficiency, whether of an organic or a neurotic origin, are benefited by the external application of cold over the cardiac area. This is evident from the improvement in the pulse rate and increased arterial pressure. It is very likely, however, that the enforced quiet to which the patient is subjected is an important factor in bringing about a favorable result. No results of an objective character can be seen in other cases of heart disease and these methods cannot compare in their efficiency with digitalis. The application of cold is agreeable to the patient, but the writer has found that equally good effects are secured when the water employed is of an indifferent temperature. The application of a certain degree of moderate pressure over the cardiac area also seems to relieve the patient to a more or less marked extent.

NEUROLOGY AND PSYCHIATRY.

Treatment of Neuralgia by Injections of Osmic Acid.—Severe cases of neuralgia frequently refuse to respond to any of the various methods of internal treatment and either become miserable morphine habitués or finally submit to a radical surgical operation, the mortality of which is considerable and the cure by no means certain. G. A. WRIGHT (*Med. Chron.*, Feb., 1904) advises a more careful use of the method by which osmic acid is injected into the nerve trunk itself after it has been exposed by dissection. He uses a one and a half or two per cent. watery solution of osmic acid and injects it directly into the nerve trunk or its branches, sometimes both toward the periphery and the center, and the acid escaping more or less freely into the tissues immediately around the nerve. He has tried this method on some thirteen cases with uniformly good results, but in many instances the length of time elasping since the treatment has been too short to make any conclusion of value. The harmlessness of the treatment, when not done in a haphazard way,' is generally conceded and should certainly be tried before resorting to such severe procedures as the excision of the Gasserian ganglion.

Paralysis Agitans After Trauma.—Traumatism is only in rare cases considered an active etiological factor in the production of this disease. K. RUHEMANN (*Berl. klin. Woch.*, April 11, 1904) states the results of careful observation on 35 cases and in 7 of these he claims that the disease could be distinctly traced to an injury. The characteristic symptoms of the trouble appeared in each case within a short time after the injury, and in few cases where there were indefinite signs before the trauma was inflicted, these grew rapidly and progressively worse soon after. The clinical picture did not vary much in the two classes of cases, but where an injury was assumed to be the cause, the disease usually appeared first in that limb which was subjected to the traumatism. In comparatively young individuals, who had been perfectly healthy before the injury, the latter can with certainty be put down as the cause for the dis-

ease, for in this instance age as predisposing factor can be excluded.

Influence of Alcohol on Cerebrospinal Pressure.—In order to measure the cerebrospinal pressure under various conditions, R. Finkelnburg (*Deutsch. Arch. f. klin. Med.*, Vol. 80, Nos. 1 and 2) introduced a trocar between the vertebræ and connected this with a manometer. After about half an hour the pressure will maintain a constant level and the action of various drugs can then be tested. If alcohol is introduced into the stomach of the animal with the stomach-tube, no change is noticed for eleven to thirty minutes. After that, the fluid will rise and then drop to the normal again in one to 3½ hours. Control animals did not show this rise and the pulse and respiration remained normal throughout the experiment. Probably the after-effects of an alcohol debauch in man, such as headache, hyperesthesia of the skin of the head, vertigo and slight stupor find their explantation in an acute hydrocephalus and general increase of cerebrospinal pressure.

PHYSIOLOGY.

Origin of Sugar from Proteid.—Considerable doubt has recently been expressed by Pflüger and his school as to whether sugar is ever formed from albumin in the animal body. Many of the apparently positive experiments must be ascribed to the presence of glycogen in the liver and muscles, and the occurrence of glucosides and glycoproteids. H. Lüthje (*Deutsch. Arch. f. klin. Med.*, Vol. 79, Nos. 5 and 6) has gone over the field anew and comes to different conclusions. A number of dogs whose pancreas had been extirpated, excreted much more sugar after the operation than could be ascribed to their glycogen or the carbohydrates contained in the food. Furthermore, a diabetic patient was kept for months on meat, eggs and coffee; as soon as casein was added to the diet, the amount of sugar in the urine increased at once. There can thus be little doubt that proteid forms one of the sources of sugar.

Effect of Drugs on the Coagulation Time of Blood.—A drug which materially shortens the time of blood coagulation would be a valuable addition to the Pharmacopœia. T. R. Boggs (*Deutsch Arch. f. klin. Med.*, Vol. 79, Nos. 5 and 6) has tried most of the substances usually recommended, chiefly with negative results. Gelatin, when injected into animals intravenously or subcutaneously, seems to have very slight or no influence, even if coagulation is first retarded by injecting leech-extract. The same may be said of gum arabic, milk, the serum of other animals, and distilled water. Even serum which had been rendered active, so that coagulation was exceedingly rapid in the test-tube, had no appreciable influence when injected. Thrombokinase, such as is obtained by macerating different organs, especially the thymus and liver, cause rapid clotting, but proved very toxic to animals. Therapeutically, the best results were always obtained with lime salts, and the lactate of calcium is especially recommended as it is almost tasteless.

Presence of Iodine in Organs.—The presence of iodine in the thyroid was regarded as peculiar for that organ, until J. Justus (*Virchow's Archiv*, Vol. 176, No. 1) showed that this element is present in all the tissues with the sole exception of the yellow bone-marrow. The liver and kidneys especially give high figures, as well as skin, hair and nails. The stomach is nine times richer in iodine than the succeeding duodenum. The simplest method of determining approximately the amount of iodine is as follows: The comminuted organ is boiled with caustic soda, evaporated and incinerated. The residue is treated with peroxide of hydrogen and water, filtered, the filtrate acidified with sulphuric acid, then treated with sodium nitrite and shaken with benzol. Free iodine will be liberated and will be taken up by the benzol. The color of the latter can then be compared with a standard solution.

Origin of Sugar from Fat.—Continued researches of H. Lüthje (*Deutsch. Arch. f. klin. Med.*, Vol. 80, Nos. 1 and 2) show that sugar may be formed in the organism from fat, as well as from proteid. An artificial glycosuria was created in a series of dogs by extirpating the pancreas. When a certain, definite amount of glycerin was added to the food, the excretion of sugar was always higher than before. The difference could not be accounted for by the glycogen present, or the amount of proteid injected.

Temperature and Secretion of the Normal Stomach.—In a patient with absolutely normal stomach, a gastric fistula had formed secondary to a severe abdominal operation. G. Galli (*Münch. med. Woch.*, April 19, 1904) used this case to determine any variation in temperature, especially in relation to food. The temperature in the empty stomach seems to be the same or slightly increased as compared with that of the full organ and no definite relation to the rectal measurements could be obtained. When the temperature inside the stomach was increased or diminished by heat or cold food, it took about an hour before normal figures were again obtained. Physiologists are of the opinion that the stomach never secretes gastric juice except in the presence of food or if stimulated reflexly by the sight or smell of food or by chewing. In the author's case, however, gastric juice was frequently found without any apparent reason for its presence. Another interesting observation was the occasional absence of free acid during the height of digestion. The following figures were obtained for total acidity: One hour after dinner, 45; three hours, 55; five hours, 65. An experiment with salol proved that this drug is never decomposed in the stomach.

HISTOLOGY, PATHOLOGY, ETC.

Fat in Blood of Immunized Animals.—Many researches have been published concerning the proteid changes in the blood of immunized animals, but M. Hahn (*Münch. med. Woch.*, April 19, 1904) was the first one to systematically investigate the fat. The extract obtained by shaking the blood with petroleum-ether was invariably greater with immunized than with normal animals, and of the many substances which are dissolved out by the ether, the fat was especially increased. There is thus a definite relation between the bactericidal power of the blood and the amount of fat it contains. The origin of the fat could not be determined; it is probably not derived from carbohydrates or proteids.

Forensic Identification of Human Blood.—In a second communication, H. Marx and E. Ehrnrooth (*Münch. med. Woch.*, April 19, 1904) lay considerable stress upon the phenomenon of isoagglutination. Human blood will frequently be agglutinated by the blood of some other human being, owing to the presence of isoagglutins, but there are marked variations in this respect, since some blood is very poor in these substances. This agglutination by homologous serum is slow; the different erythrocytes retain their contour and the hemoglobin does not dissolve out, while with heterologous serum the disintegration is complete. Isoagglutination is lost if the blood has dried for two to four weeks, while hemotcytolysis is still pronounced after three years with heterologous agglutination. The serum of an animal *A* which will agglutinate the cells of an animal *B*, will lose this property if *A* is treated with the serum of *B*. On the other hand, human serum *C*,

which will agglutinate the human cells of *D*, will agglutinate still more strongly if serum *C* is treated with serum *D*. This will afford a simple means of distinguishing between homologous and heterologous clumping. Thus, if agglutination occurs in a specimen of blood treated the usual way, it is only necessary to add a drop of diluted blood from the examiner's finger. The agglutinating serum came from a different species if the clumping is less after this addition, from the same species if it is increased. The test should always be controlled by the original Uhlenhuth reaction.

Localization of Macula Lutea in Brain.—Though the visual area of the cerebral cortex has been pretty well studied there is still considerable doubt as to which part represents the point of maximum vision in the eye. In a large monograph recently published the opinion was expressed that the anterior portion of the calcarine fissure represents the macula lutea, but an interesting case observed by L. Laquer (*Virchow's Archiv*, Vol. 175, No. 3) seems to argue more for the posterior portion. About one year before death the patient developed a bilateral hemianopsia but retained excellent vision in a small central area. At autopsy, the right occipital lobe was found softened in the neighborhood of the calcarine fissure, except in the most posterior portion, about 18 mm. from the tip of the lobe, where cortex and medullary portion were completely intact. Much the same condition was found in a second case where a bullet had pierced the back of the head. It seems a wise provision of nature that a center is located in each hemisphere.

Pathology of Cystic Kidneys.—The most peculiar feature noticed by O. Busse (*Virchow's Archiv*, Vol. 175, No. 3) while studying six fetal cystic kidneys, was the large amount of connective tissue present. The large size of the organs seems to depend more upon this than upon the cysts themselves and the entire condition would be called fibroma more appropriately than adenoma. The fibers are generally very delicate and resemble those met with in fibroma molluscum; toward the pelvis they are frequently mixed with true muscle fibers and may even contain cartilage. There is no question that the cysts originate from the glomeruli, and the papillary excrescences on the inner wall, which were formerly looked upon as confirming the adenomatous character of the growth, are merely the remains of the glomerular loop. The convoluted tubes also participate, but to a much less extent. The author does not think cystic kidneys should be classed under true tumors or that they should be looked upon as results of interstitial inflammation leading to obstruction of the apices of the papillæ, for he has made the important discovery that they bear a very close resemblance, even in minor histological details, to the normal organs of very early fetal life. If the embryonal condition remains owing to some inhibitory influence, cystic kidneys will result. During the normal process of development, the proliferating tubules will gradually replace the connective tissue until little of this is left. In many cases the patients have evidences of faulty development elsewhere, such as hydrocephalus, syndactyli and cysts in liver and pancreas. The finer structure of cystic kidneys of adults differs considerably from that of the newly born, in that there is more renal and less connective-tissue. The glomerular origin of the cysts is not so evident and they generally lack the characteristic, thick, fibromuscular wall in the cortex. Probably the condition here depends also upon a disturbance in development, but so circumscribed that only a small portion of the kidney is rendered inactive, unless the growing cysts cause compression and secondary atrophy of the adjacent tissues.

Peritoneal Exudate, an Early Symptom of Perforation Peritonitis.—Since Wegner's important work, the remarkable absorption power of the peritoneum, both for infections and intoxications, will always be regarded as definitely proven. Moszkowicz has studied this question from the clinical standpoint, his observations having been based chiefly on cases of appendicitis. C. S. Haegler (*Zntrlbl. f. Chir.*, March 12, 1904) states that he has been carrying on experimental work on animals for the last year with a view of determining what symptom became most prominent after perforation. He agrees with Moszkowicz that a serous exudate is the first recognizable factor and states that he found its quantity to be invariably in proportion to the extent or the virulence of the infection. One may consider this serous or, as it may be, hemorrhagic exudate of the peritoneal cavity a protecting factor having a double mode of action. If protection be needed against a very virulent toxin or a multiplicity of bacteria in the neighborhood of the site of infection, the exudate will be of a thin and serous character in order to dilute the toxins and the bacteria as freely as possible. Infections of a more diffuse character call for and receive less dilution and a greater amount of fibrin. It is not to be doubted that in the case of local inflammations of the bowel wall, the development of a copious amount of fluid in the peritoneal cavity is a bad prognostic sign. It shows that no tendency toward walling off has taken place and that great quantities of highly poisonous toxins or germs or both, have been liberated in the peritoneal cavity. This symptom points very persistently to a bad prognosis.

Clinical Aspects of Rheumatic Infection.—The reexaltation of the virulence of pathogenic organisms has long been a favorite topic for discussion. Carey Coombs (*Lancet*, Feb. 27, 1904) cites a large number of cases which appear to give striking corroborative evidence of this belief. He sums up his conclusions as follows: It is common to see a woman, thirty-five years of age, with mitral stenosis who has had rheumatic fever at the fifteenth or twentieth year without recurrence. The symptoms of cardiac disease often do not appear until many years after the arthritis. Necropsy shows extreme fibrosis of the mitral valve. It seems a more probable explanation of this thickening that it has been brought about by chronic irritation due to organisms of lowered virulence than that it sprang from the infection at the period of its fastigium. A case of the nature under consideration sometimes breaks out into malignant endocarditis. This is usually ascribed to reinfection of previously scarred valves, but the author cites a case in detail purporting to show that such reinfection did not occur, the disease having been awakened from resident germs of lowered vitality. The vegetations in this case contained swarms of micrococci apparently corresponding to the *Micrococcus rheumaticus* as described by recent authors. Again, relapse is common in rheumatic fever; even commoner than in enteric fever, occurring in about 20 per cent. of all cases. Rheumatic affections tend also to recur at intervals too long to call them relapses. Cases of acute rheumatic arthritis with aortic incompetence who are reported as having suffered with rheumatic fever seven or eight years before with one or two attacks in between times are not by any means rare. If such a condition is to be brought about by reinfection, it is without parallel in the history of microbic diseases. It is true that many of the infections are capable of prolonged periods of latency, to wit: Tuberculosis with its quiescent foci, *Bacillus typhosus* in bone lesions, *Bacillus coli* in the liver and gallbladder, *Staphylococci* in bone marrow, and so on. If all these organisms can remain latent, reasserting them-

selves as soon as they get a chance, why should the *Micrococcus rheumaticus* be held to differ from them in this respect?

Agglutination of Typhoid Bacilli by Other Bacteria.—That typhoid bacilli are frequently agglutinated by the serum of animals treated with the various members of the colon group is well known. D. LUBOWSKI and D. STEINBERG (*Deutsch. Arch. f. klin. Med.*, Vol. 79, Nos. 5 and 6) claim a similar action on part of a number of other bacteria. In two cases of otitic proteus infection, one of which was also complicated by staphylococcus and streptococcus infection, an agglutination of typhoid germs in a dilution of 1-80 was observed after two hours by the microscopic method. The autopsy did not reveal any lesions suggestive of typhoid and the previous history was negative. This agglutination can also be observed in some, but not all rabbits or guinea-pigs, treated with injections of proteus or staphylococcus culture. With *Streptococcus, Bacillus cholera Asiatica* and the *Bacillus fluorescens liquefaciens*, no agglutination was obtained.

OBSTETRICS AND GYNECOLOGY.

The Origin of Vaginal Cysts.—It is most difficult to classify a certain number of the cysts from the point of their origin for, says PIERRE FREDERT (*Annales de Gyn. et D'Obstetrique*, March, 1904), it is not to be shown from exact date nor can it be demonstrated that certain possibilities are probable from our anatomical knowledge. It can only be proven with certainty by their Wolffian origin (ducts and pseudoglandular canaliculi) and the vulvovaginal origin. A cyst situated high up in the vagina upon the lateral walls, may be, perhaps, Wolffian in origin; if it is situated low down, it probably is a cyst of an aberrant vulvovaginal gland. The origin of those cysts of the anterior wall is in doubt; above their origin depends upon aberrant cervicouterine glands; along the rest of the vagina near the median line, cysts take their origin from aberrant ureteral glands. Of all vaginal cysts, the most difficult to explain are those in the posterior portion of the vagina; all high up and to the side, are thought to be derived from pseudoglandular diverticula of the canal of Gärtner; to be from the canaliculi of the paraoophoron of the Wolffian body; below, on the median line, they must be considered as an embryonal cul-de-sac of Douglas; near the vulva, both anteriorly and posteriorly, are to be found vulvovaginal glands.

Abscess of the Uterus.—The development of such a condition in the wall of the uterus is of sufficient rarity to justify the publication of every undoubted instance. A. W. W. LEA (*Brit. Jour. of Obstet.*, Feb., 1904) relates a case where the abscess developed during the puerperium in a patient who was suffering from gonorrhea at the time of delivery. Its existence was not suspected until the abscess ruptured into the peritoneal cavity. Six weeks later abdominal section was performed, and the condition recognized. The patient made a good recovery. The symptoms of abscess of the uterine wall must often be obscure. As the condition is frequently complicated by intrauterine and pelvic inflammation which must render its recognition in many cases almost impossible, Von Franqué, in 15 collected cases, gives the following points as suggestive of this condition: (1) Pyrexia. This often commences suddenly, and is accompanied by rigors. There is nothing characteristic about the fever, but may continue indefinitely, especially in gonorrheal cases. (2) Pain. This is usually severe, paroxysmal in character, and felt in the lower part of the abdomen. (3) Physical signs. The uterus is enlarged, softened and very sensitive. In some cases a rounded swelling has been detected, often situated asymmetrically, and accompanied by signs of pelvic inflammation. It is obvious that these symptoms are not very definite. A small infected myoma of the uterus may produce quite similar symptoms, and it would be in many cases impossible to distinguish between this and abscess. Abscess of the uterus usually terminates by perforation, most often into the peritoneal cavity, but it may also perforate into the rectum or uterus.

Prophylaxis of Puerperal Sepsis.—In spite of the many advances which have been made toward aseptic surgery during the past two decades, we are still confronted with the deplorable fact that outside of lying-in hospitals, sepsis now claims as many if not more of the parturient mothers than it did twenty or forty years ago. G. L. BRODHEAD (*Med. Rec.*, April 23, 1904), in pointing out one of the most prolific causes of puerperal sepsis, shows that the vaginal secretion from healthy women is absolutely free from pyogenic cocci but that such bacteria are present often in large numbers upon the hymen and labia. There is no doubt that, as a rule, the germs are carried in on the examining finger and we thus find that internal examinations are undoubtedly the cause of a large number of deaths. He lays especial stress upon the fact that very few internal examinations are necessary and in many cases they need not be made at all after labor begins. The antepartum examination should be made thorough and complete to exclude, as far as possible, the chance of complications at the time of confinement. A careful external examination at the latter time will give in most cases all the information that is necessary. The diagnosis of the presentation, engagement and position can almost invariably be made out externally. The condition of the child's heart and the character of the pains will, furthermore, give fairly accurate information to an experienced person of the satisfactory progress of the case. Where internal examination is necessary he recommends the use upon the vulva of a solution consisting of chloride of lime, one teaspoonful, and acetic acid, two teaspoonfuls, to the quart of water. A solution twice as strong as the above may be advantageously used to disinfect the hands after they have been thoroughly scrubbed.

Local Anesthesia in Gynecological Operations.—That a limited sphere should be assigned to general anesthesia and more liberal use made of local anesthesia, is the suggestion made by J. C. WEBSTER (*Jour. Am. Med. Ass'n*, April 23, 1904). The former is of value in making a diagnosis in certain classes of patients, but instead of using ether or chloroform, he prefers nitrous oxide gas given with the Packard inhaler. Where extensive plastic operations are to be done, or where these may be followed by abdominal work, the Schleich solution No. 2 may be advantageously employed, a small amount of formalin being added to lessen the risk of infection. The author has performed various plastic operations on the vulva, cervix and vagina, and has also extirpated the diseased uterus and adnexa through the vagina. The abdominal operations which were done included the removal of tubes and ovaries, shortening the round ligaments, myomectomy, hysterectomy, appendectomy and resection of the intestine. A strong suggestive influence is obtained by sprinkling a few drops of chloroform on a mask held over the face. In extreme anemia and sepsis, the local anesthesia greatly diminishes the risk, and he cites a case of ruptured ectopic where the hemoglobin was less than 24 per cent. With regard to the sensibility of the various tissues, it was found that the parietal peritoneum was usually most sensitive, especially when sutured or dragged upon. Separation of adhesions between the parietes and any other structure causes pain, whereas the breaking of adhesions between viscera rarely causes distress.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the Medical News will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate, the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

SATURDAY, JULY 2, 1904.

PROPHYLAXIS OF FOURTH OF JULY TETANUS.

Shortly after the Fourth of July last year, we called attention to the large number of fatal cases of tetanus which had occurred in this country as a consequence of the celebration of the Glorious Fourth. Since then determined effort has been made in a number of parts of the country to organize rational opposition to the present methods of celebrating the Fourth, at least to bring about the amelioration of certain of the most objectionable features of the celebration. Unfortunately this movement did not meet with the success that it deserves. It is true some of the eastern cities have passed laws forbidding the sale of pistols that fire blank cartridges, and some have also made ordinances with regard to the size of the firecrackers that will be allowed to be used. Philadelphia especially, under the influence of wide-awake methods in the Board of Health, seems likely to limit fatalities.

In general, however, it would seem that nearly the same fatal results may be expected this year as last. During June and July, 1903, according to the statistics collected by the *Journal of the American Medical Association*, there were 406 deaths from tetanus and 60 deaths from other causes as the result of Fourth of July accidents due to fireworks. Besides this there were nearly 4,000 non-fatal injuries of sufficient seriousness to be reported to the police, or be received into hospital dispensaries.

The one hope is to prevent the development of tetanus in these cases, if possible, for, so far, no medical or surgical treatment of any kind seems to be effective in preventing a fatal termination if there has been serious infection by the disease. This is not hard to explain if we remember that the first symptoms of tetanus are not those of the beginning of the disease, but as has been well said by a distinguished German authority, are the first manifestations of beginning death from the disease. Last year, of all the cases of tetanus reported following injuries by fireworks, less than ten were reported as recovering. With recoveries so rare it is reasonably sure that all that actually took place found their way into the statistics, since attending physicians and surgeons would be glad of the opportunity to report them. It is very probable that some fatal cases of tetanus at least did not find their way into the statistics. The mortality then must be considered as well above 95 per cent., and recoveries were due not to any treatment employed, but to the fortunate accident of a mild infection, or some specially favoring circumstance in the method of infection or a high resistive vitality.

The prophylaxis of tetanus then becomes the great problem in the treatment of wounds received from fireworks, at this time. As far as could be ascertained of the 406 fatal cases of tetanus, 363 developed as the result of wounds inflicted by blank cartridges. Tetanus from all wounds inflicted by other kinds of fireworks, as far as could be found out, occurred in only about thirty cases. It is evident then that special attention must be given to the treatment of blank cartridge wounds. These are always deeper and more serious than they appear to be. The paper wad from the cartridge is often driven some distance into the tissues. When the wound is in the palm of the hand, as is so often the case, portions of the thick skin of the palm are usually carried with it. During the course of the celebration of the Fourth, hands are sure to be grimy with street dirt. Street dirt in our large cities always contains the tetanus bacillus. If these bacilli are thus carried deeply into the tissues then they find specially favorable circumstances for growth, in the absence of oxygen. The one absolutely necessary precaution is to clean the wound out thoroughly, removing all foreign

material and then pack it in such a manner as to allow free ingress of air and free exit for secretions.

This is not as easy always as it might seem. Portions of the wad from the blank cartridge are sometimes carried through between the bones of the hands and are driven along tendon sheaths to some distance from the point of entrance. In order to secure their thorough removal, considerable surgical manipulation of the tissues is required. As a rule, young patients will not permit this prolonged painful surgical intervention and even parents are almost sure to consider that it is unnecessary. In order to make a thoroughly satisfactory cleansing, anesthesia will usually have to be employed, especially if the wound has been inflicted by a blank cartridge pistol pointed directly and at a short distance from the tissues. Powder grains carrying dirt from the skin will also be found imbedded here and there in the tissues and must be removed for assurance sake. These wounds have been treated, heretofore, as a rule, in a superficial way and now an entirely different method must be employed.

The result of such thorough treatment has in at least one set of reported cases proven very satisfactory. Drs. Allen and Ludlow reported ten cases, treated in Cleveland last year by the painstaking method described above, and not one of them developed tetanus. Five cases on the other hand, treated superficially, and sent into the hospital afterward, all developed tetanus. Results less striking, because observations had been made on fewer cases, but quite as satisfactory in the limitation of fatality, have been reported from other parts of the country. In one case at the Massachusetts General Hospital, tetanus bacilli were even found in the secretions from the wound, but it had been thoroughly cleansed and packed so as to allow free contact with the air, and no symptoms of tetanus of the nervous system developed.

The other element in prophylactic treatment, as far as the physician is concerned, is the injection of tetanus antitoxin. It is now pretty generally conceded that though this will neutralize the toxin of the tetanus bacillus, when it can reach it directly, it is not able to undo its effects once the toxic principle has become united with the nerve cells and incipient death from tetanus has announced itself. In the immediate neighborhood of the wound, however, its injection can scarcely fail to do good by neutralizing any tetanus toxin that may be absorbed from the focus of local infection which always characterizes the development of tetanus. Thousands of injections of tetanus antitoxin have now been made without any bad results being reported, so that there need be no fear in using it freely, even to the extent of ten cubic centimeters a day for several days after the wound has been properly treated. This can scarcely fail to be an adjuvant in the treatment and add to the assurance of complete prophylaxis of tetanus of the nervous system. In horses, this method, according to Dr. MacFarland, is almost a guarantee.

An external non-medical means of prophylaxis would be the withdrawal of the permission to use toy pistols which fire blank cartridges, and the forbidding of the large giant crackers in the celebration of Independence Day. Roman candles and rockets and the small firecrackers with paper caps and torpedoes were last year responsible for none of the cases of tetanus that occurred. If the elimination of these objectionable forms of making noise, which have no special advantage in patriotic motives, could be effected, then there would be much less danger in Fourth of July wounds and much less complaint of the nuisance of the celebration. These constitute the most objectionable and least defensible features in the present method of celebrating the Fourth. Surely the common sense of the community will back up the medical profession in securing this amelioration of present conditions which is likely to have so wonderfully beneficial an effect.

MICROBES AND CANDY.

The editor of the *Ladies' Home Journal*, as we recently pointed out, has undoubtedly done a real humanitarian work by calling the attention of women generally to the patent medicine evil and pointing out how much of alcohol and opium and other undesirable drugs were being absorbed in this supposedly harmless fashion. He has very properly come to realize that much good can be accomplished by pointing out the medical dangers of other substances besides patent medicines, of which women consume large quantities. In his columns for the present month attention is very properly called to the number of evils that may flow from an excessive consumption of candy. The articles are likely to attract special attention because it is more than hinted that overconsumption of candy may readily lead to pimples and blackheads and other lesions which young women find especially undesirable. There

is no doubt that much of the unsightly acne of young growing girls is due to digestive disturbances, of which one important etiological factor is the overfree indulgence in many forms of sweetmeats now so common among the rising generation in this country.

These warnings with regard to candy are very properly found in the department of the *Ladies' Home Journal,* conducted by a physician. Some of the lessons of this department are emphasized by special editorial comment, however, and as a result we have some rather ridiculous pseudo-medicine furnished the million readers of the *Journal,* which is almost sure to do more harm than good. It seems very clear that if Mr. Bok himself writes the editorial page, and the tradition in newspaperdom is that he does, then he should have a physician, and one on whom he can depend, blue pencil his editorial effusions, whenever they touch on medical subjects, before he allows them to appear.

His readers of this month are treated to the following ludicrous exposition of the dangers of dust in candy: "A prominent physician, whose word is equivalent to that of highest authority, was standing beside the candy counter in a large department store not long ago when he said: 'Just look at those women buying that candy for themselves and their children. That candy has been exposed all day, while hundreds of people have passed by, shuffling their feet, and raising thousands of particles of dust from the floor. Most of that dust is brought from the street and contains every kind of the most dangerous germs and microbes of disease. Candy is, of course, sticky, and on account of its adhesive character everything sticks to it. Last week I came here and bought a quarter of a pound of each of four different sorts of candy which had been exposed on that counter only during the morning—just three hours, remember. I put the mass under the microscope, and amazed my clinic with what they saw. There were typhoid and malarial germs absolutely without number—the candy was literally covered with them.' "

It would be interesting to know just how the "prominent physician" succeeded in demonstrating the germ of malaria on the candy. He will confer a great favor on the medical profession of the world if he will only tell them just how the feat was accomplished. So far it has been the problem of modern medicine to discover a malarial germ outside of the bodies of animals and of certain insects. It is supposed that they do exist in some way outside of living circulating blood, but until Mr. Bok's announcement there has been no definite report of this available. If candy is the medium on which the malarial organism can be raised with ease it will not be long before all our laboratories will be furnished with a supply for the purpose of studying the stages of the life cycle of the malarial plasmodia which so far have proved rather baffling in their mysteriousness.

With regard to the typhoid fever germ we wonder just how its isolation and recognition were so readily accomplished. One of the puzzling problems of modern bacteriology has been the definite recognition of the typhoid germ from a number of organisms more or less normal to the human intestines, and which occur so commonly, is another point which we would like to have the good editor of the *Ladies' Home Journal* elucidate.

We do not think that there is a single case on record so far in which the origin of typhoid fever has been traced to the eating of candy. It is very evident that the boards of health, throughout this country especially, in our large cities have been seriously neglecting their duty in not warning people with regard to the dangers of candy, and now it would seem at last that an explanation of the many mysterious cases of typhoid fever, which have so far baffled investigation, is at hand.

The good editor of the *Ladies' Home Journal* has been tempted to use medical thunder, but evidently without quite realizing that it is loaded and that sometimes it strikes where it is least expected. The poor germ theory is responsible for enough of the ills to which this human flesh is heir without making it responsible for any more. There is no need for any exaggeration and, unfortunately, non-medical writers, when they want to emphasize a point, are almost sure to exaggerate and thus bring the germ theory into disrepute.

ECHOES AND NEWS.

NEW YORK.

Tuberculosis and City Dust.—Street Cleaning Commissioner Woodbury has made public the result of his medical examination of the sweepers of the department. Out of a total of 1,872 men 283 were found to be afflicted with pulmonary complaints. Of this number 60 had pulmonary tuberculosis. This percentage, Dr. Woodbury said, was not much above the average, but the percentage of the men found to be afflicted with the lesser forms of lung diseases and bronchial troubles was far above the average.

Miss Delano Acting Superintendent of the City Hospitals.—Miss Jane Delano, head of the training school for nurses at Bellevue Hospital, will have charge of the city hospitals during the absence of Acting Superintendent N. J. Rickard.

Care of the City Poor.—The New York Association for Improving the Condition of the Poor are doing a vast amount of good and while they are necessarily expending a large amount of money it is more than saved when it is considered that the people whom this association is helping would fall to the care of the city hospitals. The following figures taken from the *Times* show the extent of the work. Eighty-one mothers and 165 children were taken this week to their summer home at West Coney Island at a total expense of $663. The association hopes to send 13 more such groups from the crowded tenement districts. To do this will cost $8,643. Five dollars will send a mother and baby to the sea shore for a week, $10 will send a mother and three children. A bed may be named for the summer for $25. Treasurer, Robert Shaw, No. 103 East Twenty-second Street, to whom all contributions should be sent.

The Late Dr. John Metcalfe Polk.—At a meeting of the Medical Association of the Greater City of New York held June 13, 1904, the following report was presented and adopted:

It is the sad duty of the committee to report to the association the death, from pneumonia, of Dr. John Metcalfe Polk, younger son of Dr. William Mecklenberg Polk, long a practising physician of high standing in this city.

Dr. Metcalfe Polk was born on May 6, 1875. He was graduated from Yale in 1896 and from the Medical Department of Cornell University in 1899. He then entered Bellevue Hospital as interne and after remaining there two years went to Vienna to perfect himself in pathology and medical diagnosis. On his return from abroad he was appointed Instructor in Medicine and Physical Diagnosis in the Cornell Medical College and Assistant Visiting Physician to Bellevue Hospital.

At the time of his death he had just completed an exhaustive study of pneumonia. He had written and was about to publish a paper on "The Blood Changes in Pneumonia," which promised to bring to the attention of the profession some very important and original ideas.

The untimely death of Dr. Polk has removed from the ranks of the profession one of the most brilliant of its younger members. He had prepared himself through his great natural abilities and untiring energy to begin a professional life of unusual promise. At the time of his death he was pursuing with enthusiasm those branches of science the investigation of which would mean for him the broadest and most durable foundation of future success.

His gentle manners, unselfishness and sterling character had won for him warm friends among the best of the profession, both old and young. To the older men who knew him his death will mean the sacrifice of a career which the profession can ill afford to lose—to the younger, the loss of a model well fitted to inspire earnest emulation.

Resolved, That the association tender their deepest sympathy to his sorrowing father and mother, and that this note be entered on our minutes and a copy be sent to the family. Henry P. Loomis, J. Clifton Edgar, Austin Flint, Jr., Committee.

State Hospital for Tuberculosis.—The following instructions have been forwarded: The trustees of said hospital to be appointed under and pursuant to the provisions of the act of incorporation, and their successors, are hereby given power and authority to receive therein patients who have no ability to pay, but no person shall be admitted to the hospital who has not been a citizen of this State for at least one year preceding the date of application. Every person desiring free treatment in said hospital shall apply to the local authorities of his or her town, city or county having charge of the relief of the poor, who shall thereupon issue a written request to the superintendent of said hospital for the admission and treatment of such person. Such request shall state in writing whether the person is able to pay for his or her care and treatment while at the hospital, which request and statement shall be kept on file by the superintendent of the hospital. Such requests shall be filed by the superintendent in a book kept for that purpose in the order of their receipt by him. When said hospital is completed and ready for the treatment of patients, or whenever thereafter there are vacancies caused by death or removal, the superintendent shall thereupon issue a request to an examining physician, appointed as provided for in section 12, in the same city or county, and if there be no such examining physician in said city or county then the nearest examining physician, for the examination by him of said patient. Upon the request of such superintendent said examining physician shall examine all persons applying for free admission and treatment in said institution, and determine whether such persons applying are suffering from incipient pulmonary tuberculosis. No person shall be admitted as a patient in said institution without the certificate of one of said examining physicians certifying that such applicant is suffering from incipient pulmonary tuberculosis. Admission to said hospital shall be made in the order in which the names of applicants shall appear upon the application book to be kept as above provided by the superintendent of said hospital, in so far as such applicants are subsequently certified by the said examining physician to be suffering from incipient pulmonary tuberculosis. Every person who is declared as herein provided to be unable to pay for his or her care or treatment shall be transported to and from the hospital at the expense of said local authorities. *Private Patients.*—Applicants for admission to this institution who are able to pay for their care and treatment are not required to obtain a written request from the local authorities having charge of the relief of the poor, but shall apply in person to the superintendent who shall enter the name of such applicant in the book to be kept by him for that purpose, as provided in section 13; and when there is room in said hospital for the admission of such applicant, without interfering with the preference in the selection of patients, which shall always be given to the indigent, such patients shall be admitted to the hospital upon the certificate of one of the examining physicians, which certificate shall be kept on file by the said superintendent. *Support of Free Patients.*—At least once in each month the superintendent of the hospital shall furnish to the comptroller a list countersigned by the treasurer of the hospital of all the free patients in the hospital, together with sufficient facts to enable the comptroller to collect from the proper local official having charge of the relief of the poor such sums as may be owing to the State for the examination, care and

treatment of the patients who have been received by the hospital and who are shown by the statement of such local official to be unable to pay for their care and treatment. The comptroller shall thereupon collect from the said local official the sums due for the care and treatment of each such patient at a rate not exceeding $5 per week for each patient. *Support of Private Patients.*—The trustees shall have power and authority to fix the charges to be paid by patients who are able to pay for their care and treatment in said hospital or who have relatives bound by law to support them, who are able to pay.

Transfer of Sanitary Inspectors.—Commissioner Darlington transferred all the five sanitary superintendents in the Greater City last week. "For the good of the service," is the reason ascribed by Dr. Darlington. The changes were: Dr. Patrick J. Murray, from Brooklyn to Queens; Dr. Walter Bensel, from Manhattan to Brooklyn; Dr. Gerald Sheil, from the Bronx to Manhattan; Dr. John T. Sprague, from Richmond to the Bronx; Dr. John P. Moore, from Queens to Richmond. When Dr. Darlington was questioned to-day about the changes he declined to discuss them other than to say they were made "for the good of the service," in the department—the stereotyped reason. The order went into effect to-day. Dr. Bensel, who took charge of the Brooklyn office immediately, laughed at the idea that there had been any politics in the shake-up. "I'm no politician myself," said he, "but I don't see where the politics comes in on this. There have been other shake-ups just like this one. There was one last summer. I got a taste of Brooklyn, and later was sent to Queens, the Bronx, and Richmond in succession. It has been the custom to give all the assistant sanitary superintendents a chance to get acquainted with the work in Manhattan. Whenever a new man is put in there everybody moves along."

PHILADELPHIA.

Surgeon General of Pennsylvania.—Dr. Joseph K. Weaver, of Norristown, has been promoted from division surgeon of the Pennsylvania National Guard to surgeon-general and chief of the medical department, with the rank of colonel. Major G. H. Halberstadt, of Pottsville, has been reappointed surgeon of the Third Brigade and Dr. J. C. Biddle assistant surgeon of the Eighth Regiment.

Tablets in Honor of Noted Physicians.—Memorial tablets to Drs. S. Weir Mitchell and Horatio C. Wood have been placed in the new medical laboratories of the University of Pennsylvania. The former was erected by Provost and Mrs. C. C. Harrison; that to Dr. Wood was dedicated to him by the trustees of the university in recognition of his services to the institution.

To Prevent Fourth of July Casualties.—The State Board of Health has sent a communication to the Mayor or Chief Burgess of every city and township in the State calling attention to the laws regarding the sale and use of firearms and fireworks; this is for the purpose of diminishing if possible the mortality from Fourth of July accidents.

Appointment of Dr. Lloyd.—Dr. James Hendrie Lloyd has been appointed visiting neurologist to the Philadelphia Hospital at Blockley. Dr. Lloyd formerly served on the nervous staff for thirteen years, but resigned in 1900.

CHICAGO.

Commencement Exercises of Rush Medical College.—This college, which is affiliated with the University of Chicago, held its commencement exercises June 15, when degrees were conferred on a class of 107. The Doctorate address was delivered by Dr. Charles G. Stockton, of Buffalo, N. Y.

Increased Endowment.—The Chicago-Farmington Society held a lawn fête in Winnetka recently, at which $2,000 was raised to complete the endowment of the Sarah Porter room in the Passavant Memorial Hospital.

Election of Dr. Murphy.—Dr. John B. Murphy, of this city, was recently elected President of the Chicago Medical Society.

GENERAL.

World's Fair Emergency Hospital Library.—The **Medical News** may be found on file in the library of the Emergency Hospital at St. Louis this summer.

Sanitation at Panama.—Aboard the Panama Railroad steamship Alliança, which sailed last week for Colon, were Chief Engineer J. F. Wallace and Dr. W. G. Gorgas and a staff of sanitarians and nurses who are going to do preliminary work on the Panama Canal route. Dr. Gorgas said that within a year he would have the canal strip as healthful as Cuba. He will establish sewerage and drainage systems and exterminate mosquitoes and other disease carrying insects. A call will presently be issued for volunteer physicians and surgeons to serve in the Panama Canal zone under contract with the Government. The Army and the Navy Departments will assign surgeons and doctors to duty in this region, but as there are to be not less than 50,000 men employed in the canal construction work, it is evident that outside medical aid will very soon be needed. This need opens an opportunity for graduates from medical schools who have not yet established themselves in practice. These should be physically sound young men with a good knowledge of medicine and surgery, and well qualified in the specialties of hygiene and modern sanitary science. The service involves serious risks, but no true physician ever hesitated to devote his life to the duty of alleviating the ills that flesh is heir to in obedience to the call of his perilous profession.

Census Returns.—An abstract of the census for 1900 has just been made public. Among the many significant facts to be obtained by an analysis of the figures a few bearing on medico-social topics are noteworthy. Some on marriage show that akin to the distribution among families is the matter of marital condition. In 1900 the percentage of married among all persons fifteen years or older was 55.5; of single, 36; of widowed, almost eight per cent., and of divorced, four-tenths of one per cent. To judge from the figures the coast States are the best for marriageable women, 60 per cent. being wives against 59 per cent. in the Central West and 54 per per cent. in the East. Contrariwise the Pacific coast shows the smallest per cent. of married men, 45 per cent., against a general average of 55 per cent. in the East and Middle West. Of all the States in the Union Vermont has the smallest per cent. of unmarried males over fifteen years of age, 35 per cent. Maine is not far behind with 36. The national average exceeds 40 and New York State is below it, 37.6. Of unmarried women New Mexico has less than 20 per cent., as compared with an average of 31 for the country. Massachusetts has the largest number of bachelor girls, 37 per cent., followed closely by Rhode Island, and then, strangely enough, by Virginia and Maryland. A total of 1,178,000 widowers is reported in 1900, as against a total of 2,717,000

widows. The number of divorced men, still unmarried, was 84,000 and the number of divorced women was 114,000. It is not surprising that density of population in the East is becoming one of the notable features of American life. Rhode Island has 407 persons to every square mile, and Massachusetts follows closely with 348. New York has but 152, but her per cent. of increase in population is rapidly rising, being three per cent. in 1890-1900 above that of the previous decade and five per cent. above that of 1870 to 1880. At the present time there are living in the so-called rural districts of New York State barely 27 per cent. of her population. This is far greater than the record in Rhode Island, of five per cent., or of Massachusetts with 8.5, toward which the trend is very rapid.

Trend in Mortality Statistics. — Among other striking facts brought into prominence by the last census it is demonstrated by exact figures from a so-called "registration area," comprising those sections of the United States which have accurate reports, that the increase in pneumonia deaths from 1890 to 1900 was five per cent., of heart disease 12 per cent., of kidney disease 44 per cent., of apoplexy 17 per cent., and of cancer 12 per cent. On the other hand, the figures show a decrease in deaths from consumption of nearly 55 per cent. and of bronchitis 26 per cent. A marked illustration of the effect of better knowledge of infantile diseases and the growing use of antitoxin is the large decrease in deaths from those causes. Thus the decrease in deaths from cholera infantum from 1890 to 1900 was 31 per cent., of diphtheria 34 per cent. and of convulsions 23 per cent. Some rather common ideas as to the prevalence of diseases in certain sections are dispelled by these figures. Consumption, supposed to be a cold climate disease, had in 1900 an average number of deaths in New York State of 194 to 100,000 population. In the same year this disease had in Vermont, a much colder State, 152 deaths to 100,000 population, and in the District of Columbia, a much warmer place, 305 deaths to 100,000 population.

Medical Department of the Congress of Arts and Sciences at St. Louis.—The plan and purpose of this Congress deviate so far from traditional lines that some explanation may be necessary to show how it should interest the medical profession. It is primarily a congress of scholars rather than of specialists. It is divided into 24 departments, one of the strongest of which is Medicine. Yet it is not intended to be a distinctly medical assemblage, but, as we have indicated, a congress of medical scholars. The Department of Medicine is divided into 12 sections, embracing the principal fields covered by the subject. These do not include Embryology, Anatomy, Physiology or Bacteriology,—subjects which are embraced in the department of Biology,—but which, it may be expected, will be of equal interest to medical scholars. The order of proceedings will be most easily understood if set forth in detail. The Department of Medicine will be opened on Tuesday, September 20, under the chairmanship of Dr. William Osler, with two general addresses by Dr. W. T. Councilman, of the Harvard Medical College, and Dr. Frank Billings, of the Rush Medical College. One of these speakers will review the progress of Medicine during the past century, and the other will treat its fundamental conceptions. On Wednesday morning, September 21, a section of Public Health will meet under the presidency of Dr. Walter Wyman, Surgeon-General of the U. S. Marine Hospital Service. It will be addressed by Professor W. T. Sedgwick, of the Massachusetts Institute of Technology, and Dr. Ernst J. Lederle, formerly Commissioner of Health of New York City. Communications relating to the subject are also expected from several eminent members of the profession. A section of Otology and Laryngology will meet at the same time: Chairman, Dr. Glasgow, of St. Louis; principal speakers, Sir Felix Sémon, of London, Physician Extraordinary to the King, and Dr. J. Solis-Cohen, of Philadelphia.

In the afternoon a section of Preventive Medicine will meet, under the chairmanship of Dr. Mathews, President of the Kentucky Board of Health. It will be addressed by Professors Ronald Ross, of Liverpool, and Celli, of Rome. Some question has been raised against the advisability of separating these two sections. This separation is, however, of no practical importance, as all interested may equally well attend both. At the same time with Preventive Medicine, a section of Pediatrics will meet under the chairmanship of Dr. Rotch, and will be addressed by Escherich, of Vienna, Jacobi, of New York, and others. On Thursday morning, there will be meetings of sections of Pathology and Psychiatry. The chairmen of these sections are Drs. Simon Flexner and Edward Cowles. Marchand, of Leipzig, and Orth, of Berlin, accepted invitations to address the section of Pathology, but it is not certain whether both will be able to attend. Psychiatry will be treated by Ziehen, of Berlin, and Dana, of New York. In the afternoon a section of Neurology will meet, under the chairmanship of Professor L. F. Barker, of Chicago, and will be addressed by Kitasato, of Tokio, and Putnam, of Boston. It seems hardly necessary to enter with like detail into the proceedings of the remaining sections on Friday and Saturday. It will suffice to copy the subjects, chairmen and speakers from the program, as follows:

Therapeutics and Pharmacology.—Chairman: Dr. Hobart A. Hare, Jefferson Medical College. Speakers: Sir Lauder Brunton, F.R.S., London; Professor M. E. O. Liebreich, University of Berlin.

Internal Medicine (Friday afternoon).—Chairman: Professor F. C. Shattuck, Harvard University. Speakers: Professor Clifford Allbutt, F.R.S., University of Cambridge; Professor W. S. Thayer, Johns Hopkins University.

Surgery (Friday morning).—Chairman: Professor Carl Beck, Post-Graduate Medical School, New York. Speakers: Professor Frederic S. Dennis, Cornell Medical College, New York. (Not finally selected.)

Gynecology (Saturday morning).—Chairman: Professor Howard A. Kelly, Johns Hopkins University. Speakers: Dr. L. G. Richelot, Member of the Academy of Medicine, Paris, France; Professor J. C. Webster, Rush Medical College, Chicago.

Ophthalmology (Saturday afternoon).—Chairman: Dr. G. C. Harlan, Philadelphia, Pa. Speakers: Dr. Edward Jackson, Denver, Colo.; Dr. George M. Gould, Philadelphia, Pa.

On the general plan of the Congress, one of the two principal speakers in each section will treat of the relation of the subject to other departments of knowledge; and the other, of its present problems. Besides the principal speakers, it is expected that each section will receive several brief communications from leading members of the profession in attendance at the meetings.

It will be seen that the division into sections is one of subjects rather than of men. The chairmen and speakers will be different in different sections.

but the attendance will be the same, except in the sections holding their meetings at the same time.

It is hoped that this program will prove attractive to such leading members of the medical profession in America as may be able to visit St. Louis and take part in the proceedings of the Congress.

Examination for Army Medical Service.—The examination of applicants for commission in the Medical Corps of the Army will be materially modified after July 1, 1904, when the amended regulations governing the matter will go into effect. Immediate appointment of applicants after successful physical and professional examination—the latter embracing all subjects of a medical education—will be discontinued; thereafter applicants will be subjected to a preliminary examination and a final or qualifying examination with a course of instruction at the Army Medical School in Washington intervening. The preliminary examination will consist of a rigid inquiry into the physical qualifications of applicants and written examination in the following subjects: Mathematics (arithmetic, algebra and plane geometry); Geography; History (especially of the United States); Latin grammar and reading of easy Latin prose; English grammar (orthography, composition); Anatomy; Physiology; Chemistry and Physics; Materia Medica and Therapeutics; Normal Histology. The subjects in general education above mentioned are an essential part of the examination and cannot under any circumstances be waived. The preliminary examination will be conducted concurrently throughout the United States by boards of medical officers at most convenient points; the questions submitted to all applicants will be identical thus assuring a thoroughly competitive feature, and all papers will be criticised and graded by an Army Medical Board in Washington. Applicants who attain a general average of 80 per cent. and upwards in this examination will be employed as Contract Surgeons and ordered to the Army Medical School for instruction as candidates for admission to the Medical Corps of the Army: if, however, a greater number of applicants attain the required average than can be accommodated at the school the requisite number will be selected according to relative standing in the examination. The course of instruction at the Army Medical School will consist of lectures and practical work in subjects peculiarly appropriate to the duties which a medical officer is called upon to perform. While at this school the students will be held under military discipline, and character, habits and general deportment closely observed. The final or qualifying examination will be held at the close of the school term and will comprise the subjects taught in the school together with the following professional subjects not included in the preliminary examination: Surgery; Practice of Medicine; Diseases of Women and Children; Obstetrics; Hygiene; Bateriology and Pathology; general aptitude will be marked from observation during the school term. A general average of 80 per cent. in this examination will be required as qualifying for appointment, and candidates attaining the highest percentages will be selected for commission to the extent of the existing vacancies in the Medical Department. Candidates who attain the requisite general average who fail to receive commissions will be given certificates of graduation at the school and will be preferred for appointment as medical officers of volunteers or for employment as contract surgeons; they will also be given opportunity to take the qualifying examination with the next succeeding class. It is not thought that, for the present at least, the number successfully passing the preliminary examination will be greater than can be accommodated at the Army Medical School, nor that the number qualifying for appointment will exceed the number of vacancies. If, however, the class of candidates qualifying should be larger than reasonably thought, the young physicians who fail to receive commissions will not have wasted their time, as the course of instruction at the school, while in a large measure specialized to army needs, is such as will better fit them for other professional pursuits, and furthermore they will have received a fair compensation while under instruction. Admission to the preliminary examination can be had only upon invitation from the Surgeon-General of the Army, issued after formal application to the Secretary of War for permission to appear for examination. No applicant whose age exceeds thirty years will be permitted to take the examination, and the authorities at the War Department desire it distinctly understood that this limit of age will be rigidly adhered to. Hospital training and practical experience are essential requisites, and an applicant will be expected to present evidence of one year's hospital experience or its equivalent (two years) in practice. The first preliminary examination under the amended regulations above referred to will be held about August 1, 1904; those desiring to enter the same should at once communicate with the Surgeon-General of the Army, Washington, D. C., who will be pleased to furnish all possible information in regard thereto.

Boric Acid in Food.—The Department of Agriculture has just issued, writes the *Tribune*, a report giving the result of the experiments made last year in the influence of boric acid and borax on digestion and health. During a period of six months 12 young men submitted themselves to the observation of experts and gave a test of the effect of natural and preserved foods upon the system. The trial seems to have demonstrated that, while the human body can endure considerable quantities of boric acid in food without serious results, yet the steady absorption of the drug is unhealthful and especially likely to work injury to persons of a delicate constitution. The report shows that boric acid taken in food is eliminated from the system almost entirely by the kidneys, and that, as the maximum traces of it are found only three days after administration, the drug meanwhile is present in the circulation. It is not shown that the boric acid has any directly deleterious effect upon the kidneys, but anybody who realizes the prevalence of kidney disease under the unnatural strain upon those organs of the common mode of life, with its nervous tension and overeating, will feel it unwise to subject them unnecessarily to the work of eliminating from the body a chemical product which has no natural place there and with which they should not be called upon to deal. The department further finds that the continued use of boric acid, even in small quantities which produce no immediate palpable effects and are not noticeable to the taste, results in loss of appetite, bad feeling, fulness in the head and distress in the stomach. Persons regularly using borated food tend to lose weight, and analysis shows that a smaller proportion of borated than of natural food is digested and made available for the body's uses. The report is thoroughly conservative. It makes no sensational charges that food is poisoned by borax. It admits that articles of only occasional use may be preserved with the aid of boric acid without harm, and it con-

cedes that meats shipped raw and not kept too long may without bad results receive an external coating of preservative which excludes germs of decomposition without penetrating far beneath the surface. Nevertheless, it is emphatic in its warning against the habitual use of preserved foods, and in its demand that such foods be honestly labeled that the consumer may know what he is getting. This phase of the subject is particularly important. The consumer is now at the mercy of the producer. If he is an invalid, he may be seriously injured by borated foods which he buys, supposing them to be pure. He should have a chance to know whether he is getting natural or preserved food. If his constitution will stand the latter, well and good. If it will not, what is to him a poison should not be secretly and fraudulently administered to him. It may be that for the preservation of some articles boric acid is necessary, or at least preferable to the chemical conditions which would be developed without antiseptic properties.

The burden of proof on that point, however, rests upon the producer. He should be compelled to meet this obligation, to specify his use of boric acid and commend it to favor, and not allowed to sell goods under false pretenses. The report says: "It is undoubtedly true that no patent effects may be produced in persons of good health by the occasional use of preservatives of this kind in small quantities, but the young, the debilitated and the sick must not be forgotten, and the safe rule to follow is to exclude these preservatives from foods for general consumption." This can only be done by compelling publicity in the use of the preservatives. Otherwise, in spite of all precaution, those who would be injured will unwittingly use them to the detriment of their health.

Crime Among the Colored Race.—At the last annual meeting of the National Society of Charities and Correction, held last week, among the interesting papers was one on this subject. Quoting the statement that a single sentence to the chain gang, no matter how trivial the offense, usually makes the victim a criminal for life. William E. Benson, superintendent of Kowaliga Institute, Ala., made a plea for educational measures of the right sort in preventing crime among colored people. He presented a study of conditions in a small Alabama community where two-thirds are negroes which apparently flatly contradicted the old charge, that among them education and criminality go hand in hand. "In the distant rural communities of the South," said Superintendent Benson, "there are no organized charities, no institutions for rescue work, no juvenile reformatories for colored children, consequently the schools and churches must be the source of their moral uplift and inspiration. Negro boys and girls who are criminally inclined must either find their regeneration in private schools or eventually on the prison farm. Therefore the necessity for systematic preventive effort is pressing because when they once commit crime, little discrimination is made in their punishment. It is meted out according to their crime rather than their criminal record. The young and careless mischiefmaker is imprisoned in the same cell and confined to the same prison farm as the old and hardened thug. It is asserted upon good authority that a single sentence to the chain gang usually makes the victim a confirmed criminal for life. In considering the factors of preventive work, let us first determine what are the uplifting influences in communities where dependency and delinquency have been reduced to a minimum, and then introduce as fast as possible these conditions into other communities. Let us ask who are the negroes that commit crime and go to prison. Are they really the educated, self-respecting and industrious who have learned to use their hands and brains in making an honest livelihood, or, do they come from the class who are shiftless, lazy and illiterate?

"In my own community in Alabama, we maintain a good school which gives not only an English education, but seeks to train boys and girls to do intelligently and profitably the common work of life. There have been 42 arrests within the last eight years—35 negroes and seven whites. These were all cases which came within the jurisdiction of the local magistrate and were of a comparatively trivial nature. The charges were as follows: Road defaulters 3, defamation 1, disposing of mortgaged property 2, assaults to murder 17, cruelty to animals 2, bastardy 1, obtaining goods under false pretenses 1, disorderly conduct 1, arson 2, petty larceny 8, carrying concealed weapons 1, vagrancy 1, alleged assault to rape 11, manslaughter 1. In the cases of the latter two charges, the defendants were acquitted on account of lack of evidence. Only one of these arrests was committed to jail and he was never sentenced, the prosecution failing to appear. There has not been a single murder case, with the exception of an accidental killing, within the last ten years and not one of our race has ever been convicted for rape or any serious crime whatsoever within the last twenty years.

This record includes a small community two and a half miles square where nearly two-thirds of the population are negroes. Further out into the county around us, where there are no schools, we find the record of both races running the whole gamut of crime from petty larceny to murder. There have been in all 125 convictions in the county between the years 1900 to 1904, 105 negroes and twenty whites. Out of 47 convicted, 20 were sentenced to hard labor for the county for terms of two to six months and 27 to the state penitentiary for terms of from one to twenty years. Seventy misdemeanors were committed by negroes and four by whites in the same period, while 16 felonies were committed by whites and 35 by negroes. In other words, the rate of criminality among negroes, which is very high in the lighter offenses, decreases in the deeper crimes, while the rate among the whites, which is very low in the lighter offenses, increases in the deeper crimes.

OBITUARY.

Dr. John H. Dorn, whose home for many years was at 39½ Washington Square South, New York City, died suddenly in London on Friday of heart disease. He retired from active practice eight years ago, largely on account of his health. Dr. Dorn, who was born in Johnstown, N. Y., in 1842, entered the Union Army at the outbreak of the war, and served two years with a New York regiment. He went to Albany at the conclusion of his military service, and entered the Albany Medical College, from which he was graduated in 1865. He began practising in the Fifteenth Ward in this city, and in 1875 was appointed a police surgeon. He was retired as such in 1896. For twenty-five years he was Secretary of the Lincoln Club of the Fifth Assembly District.

Dr. L. A. Lowden, of Indianapolis, died June 21 at his home.

CORRESPONDENCE.

OUR LONDON LETTER.

LONDON, June 4.

INTERIM REPORT OF THE ROYAL COMMISSION ON TUBERCULOSIS—THE PURSUIT OF NOVELTIES IN MEDICINE—MEDICAL OFFICERS OF HEALTH—"EUGENICS"—HYGIENE IN THE HAIRDRESSER'S SHOP.

IMMEDIATELY after Koch's subversive address on human and bovine tuberculosis at the Congress held here in 1901 a Royal Commission was appointed to study the whole question. The Commissioners chosen were Sir Michael Foster, Professor of Physiology at Cambridge, Chairman; Dr. Sims Woodhead, Professor of Pathology in the same university; Dr. Sidney Martin, Professor of Pathology, University College, London; Dr. John McFadyean, Professor of Comparative Pathology in the Royal Veterinary College, and Dr. Boyce, Professor of Pathology, University College, Liverpool. The specific questions which they had to consider were the following: (1) Whether the disease in animals and man is one and the same; (2) Whether animals and man can be reciprocally infected with it; (3) Under what conditions, if at all, the transmission of the disease from animals to man takes place, and what are the circumstances favorable or unfavorable to such transmission. They decided that their best course would be to begin their work, not by collecting opinions, but by making experimental investigations for themselves. Their first line of inquiry was to discover the effects produced by introducing into the body of the bovine animal (calf, heifer, cow) either through the alimentary canal as food, or directly into the tissues by injection, tuberculous matter of human origin, *i.e.*, material containing living tubercle bacilli derived from various cases of tuberculous disease in the human subject; and how far those effects resemble or differ from the effects produced by the introduction into the bovine animal under similar conditions of tuberculous matter of bovine origin, *i.e.*, material containing living tubercle bacilli obtained from cases of tuberculosis in the cow, calf, or ox. The Commission has been at work for nearly three years, and we had begun to wonder whether it was to sit as long as the last Vaccination Commission to which at one time it seemed that the description of Theseus in Tartarus, *Sedet aeternumque sedebit,* might be applicable. The publication of an interim report on June 1 therefore came as a surprise. The Commissioners say they have been moved to make their results known in this way because they are so striking. Their experiments, details of which are reserved for a further report, have led them to the conclusion that "tubercle of human origin can give rise in the bovine animal to tuberculosis identical with ordinary bovine tuberculosis." In their experiments they made use of more than twenty different "strains" of tuberculous material of human origin and two hundred animals. They compared the effects produced by these with the effects produced by several different strains of tuberculous material of bovine origin. In the case of seven of the "strains" of human origin, the introduction of the human tuberculous material into cattle at once gave rise to acute tuberculosis, the disease in some instances being of great severity. In the case of the remaining strains, the bovine animal into which the tuberculous material was first introduced was affected to a less extent. Nevertheless, tuberculous material from the bovine animal thus affected introduced into other bovine animals and into guinea-pigs, in the case of five of these strains ultimately gave rise in the bovine animal to general tuberculosis of an intense character. The Commissioners say: "We have very carefully compared the disease thus set up in the bovine animal by material of human origin with that set up in the animal by bovine material, and so far we have found the one, both in its broad general features, and in its finer histological details, to be identical with the other. We have so far failed to discover any character by which we could distinguish the one from the other. The result at which we have arrived seems to us to show quite clearly that it would be most unwise to frame or modify legislative measures in accordance with the view that human and bovine tubercle bacilli are specifically different from each other, and that the disease caused by the one is a wholly different thing from the disease caused by the other." Briefly put, the conclusion of the British Commission is against Koch's view that human beings are but slightly, if at all, susceptible to infection by bovine tuberculosis, and that the danger from the milk of a tuberculous cow is so small as to be practically a negligible quantity. It may be recalled that these views caused a great sensation at the Congress, as doubtless they were intended to do. As soon as Koch sat down, Lister rose and said that if the conclusions of the German investigator were correct, the means of preventing tuberculosis would be greatly simplified; but, on the other hand, it would be a very serious and grievous matter if the endeavors which were being made to provide purity of milk supply should be relaxed, and that then the conclusion should be found not altogether correct. For his own part he must frankly say that the evidence which Professor Koch had brought forward was not very satisfactory. The dairymen were of course greatly pleased at the prospect opened up by Koch's deliverance of a relaxation of the stringent supervision of their products now enforced by law. Medical opinion however was strong enough to prevent any action in that direction being taken till conclusive evidence in support of Koch's teaching was forthcoming.

Sir Dyce Duckworth, one of the pillars of that dignified but somewhat effete institution, the London College of Physicians, has lately delivered his soul in denunciation of "the modern pursuit of novelties in medicine." He thinks physiology as now taught by specialists is too purely scientific to be of much use to practitioners, and occupies too large a space in the medical curriculum. On the other hand he complains that the study of botany is hardly reckoned within the compass of modern medical education. He rarely comes across a pupil who knows the natural order of plants or could name properly any of our common hedgerow flowers. He regards this as a lamentable decadence and a distinct loss since he has always reckoned a training in botany as one of the very best for the future medical man. In this Sir Dyce Duckworth is in direct opposition to Huxley who proposed to lighten the course of studies by throwing overboard not only botany but zoology and even materia medica which he said was as unnecessary to a physician as a knowledge of cutlery to a surgeon. Duckworth has a good word to say for bleeding in suitable cases and he points to the fact that the oculist who sees what he is doing better than the physician never gave up the practice in deference to those who condemned it as an enfeebling procedure. He admits that mercury was grossly abused in the good old days, but he thinks that the calomel which our predecessors employed was a more efficient drug than "the chemically, perhaps too chemically, pure salt" used to-day. Duckworth mourns the passing of John Abernethy's famous blue pill and black draught, which have been replaced, "often inefficiently," by doses of aperient waters. He also finds comfort in that blessed word "diathesis" at which modern science is too apt to point the finger of scorn. The most mis-

chievous element in our modern system of therapeutics, however, is declared to be "a perpetual pursuit of novelties, an untiring effort to produce new remedies, the enjoining new methods of dietary, and with all this, the inevitable loss of any well-acquired principles of treatment as founded on long experience of others, or of personal experience laboriously acquired for oneself." Duckworth plaintively says that he is always meeting with perscriptions composed of many drugs of whose existence he has no knowledge, and which are in no pharmacopœias. Every week he is informed from German and American sources of some new synthetical compounds and so-called foods, generally with unpronounceable names, which he is invited to use on the strength of monstrous assertions and the raw experience of some young and imperfectly-trained physicians. It is all very sad and very bad, and unworthy of well-trained practitioners. The pity of it is "we have frivolous minds amongst us at work in therapeutics." There is of course a large amount of truth in this, but the Athenian curiosity to hear of some new thing is by no means exclusively modern. Did not old Broussais, speaking of new specifics say, *Hâtez-vous de prendre ce remède pendant qu'il guérit?* Duckworth urges strongly the value and importance of practitioners acquiring a full knowledge of the pharmacopœia, and of the art of prescribing appropriately. As an examiner he is constantly aghast at the ignorance of these subjects displayed by candidates. There are, he says, fashions in diseases as in drugs. "To-day we find weak hearts asserted to be very prevalent; lately gastric dilatation was perpetually before us; then neurasthenia; next, phimosis became of extraordinary frequency, while typhlitis and nasopharyngeal adenoid growths are heard of on all sides in society. To-morrow there will be something else." But we must be calm, and level-headed, to see all things in due proportion, to hold fast by all we have learned to see as most certain and dependable in medicine. In expressing these sentiments Duckworth declines to be regarded as an old Tory in medicine, or a pre-scientific fossil. Well, we need not call him a fossil; he is only a particularly fine specimen of British Conservatism.

Medical officers of health are not only very poorly paid, but hold their appointments for the most part from year to year and therefore at the mercy of the sanitary authorities whose servants they are. This fact goes far to nullify their usefulness to the public. If a zealous officer is impelled by his conscience to condemn houses or tenements as unhealthy, he naturally makes enemies of the owners of the property who often are members of the body which appoints him. Quite recently an able officer to an out-lying London borough, who had reported adversely on certain foods submitted to him by the inspector, was refused re-election. It happened that the seizures had been made from the premises of the chairman of the health committee, who had used his influence to supplant the doctor. Insanitary areas have been passed over by inspectors under fear of dismissal, and when the medical officer has dared to report he has been deprived of office. A notorious scandal arose in a seaside town where the mayor had concealed the fact that his two daughters and a servant were down with smallpox. Certain troubles ensued, and the local officer, having had his attention called to the matter, made his report. Within a month he was not only dismissed from his office, but this adverse vote made longer stay in the borough utterly impracticable. In another case a clever young practitioner was literally hounded out of a small South Wales district because he attributed a certain epidemic of fever to the use of water on a certain nobleman's estate, and forwarded samples together with his report to the Local Government Board. From these facts, which could be multiplied indefinitely, it is evident that in the interest of the public health it is imperatively necessary that medical officers of health should be independent of the malice or whims of sanitary authorities which are largely composed of local tradesmen and owners of house property and should be made secure in the tenure of their office. The Incorporated Society of Medical Officers of Health is therefore taking action to secure this. The attention of Parliament is to be called to the subject and there is a good prospect of the desired reform being effected, as it has the support of Mr. Arthur Balfour, the Prime Minister, Sir Michael Hicks-Beach, the late Chancellor of the Exchequer, and Sir Walter Foster, ex-Parliamentary Secretary of the Local Government Board. In 1869 the Royal Sanitary Commission recommended fixity of tenure, but the recommendation has been allowed to remain the expression of a pious opinion.

Mr. Francis Galton whose name is well-known by his researches on finger marks and his studies of various problems of heredity, recently delivered an address on "Eugenics," which he explained to be the science which dealt with all influences that improved the inborn qualities of a race, and with those that developed these qualities. The aim of eugenics, he says, was to bring as many influences as could be reasonably employed to cause the useful classes in the community to contribute more than their proportion to the next generation. It seemed to be the tendency of high civilization to check fertility in the upper classes, through numerous causes, some of which were well known, others were inferred, and others, again, were wholly obscure. But it might be expected that types of our race would be found to exist which could be highly civilized without losing fertility, and they might even become more fertile under artificial conditions, as was the case with domestic animals. If marriages unsuitable from the eugenic point of view were banned socially, or even regarded with the unreasonable disfavor which some attached to cousin marriages, very few such unions would take place. The improvement of our stock seemed to Mr. Galton one of the highest objects we could reasonably attempt. He saw no impossibility in eugenics becoming a religious dogma among mankind, but its details must first be worked out sedulously in study. The first and main point was to secure the general intellectual acceptance of eugenics as a hopeful and most important study. In the discussion which followed Mr. Benjamin Kidd (author of *Social Evolution*) pointed out that much obscurity at present existed in sociological studies from confusing two entirely different things—namely, individual efficiency and social efficiency. Judging from what one sometimes read, many of our ardent reformers would often be willing to put us into lethal chambers if our minds and bodies did not conform to certain standards. Our methods of knowledge were as yet admittedly very imperfect. He believed that much that Mr. Galton anticipated would be realized. But he thought we must go slowly with our science of eugenics, and that we must take care, above all things, that it advanced with, and did not precede, a real science of our social evolution. Even the highest representatives of the various social sciences must realize that, in the specialized study of sociology as a whole, they were scarcely more than distinguished amateurs. Otherwise, in few other departments of study would there be so much danger of incomplete knowledge, and even of downright quackery, clothing itself with the mantle and authority of science. Mr. H. G. Wells expressed the belief that the conscious selection of the best for reproduction would be impossible, and that to propose it was to display a fundamental misunderstanding of what individuality

implied. It was in the sterilization of failures, and not in the selection of successes for breeding, that the possibility of an improvement of the human stock lay.

Dr. Collingridge, Medical Officer of the City of London, has recently grappled with a somewhat difficult problem. He proposes to establish a code of regulations to secure antisepsis in the hairdresser's shop. Shaving brushes are to be dipped in an antiseptic solution before use; the operators, or "artists" as they call themselves, are to put on a fresh apron for each customer; razors are to be sterilized and hairbrushes are to be washed after use. The hair-dressing fraternity as a class do not view these proposals with favor, and it remains to be seen whether the City Fathers are sufficiently progressive to support their health officer.

SOCIETY PROCEEDINGS.

AMERICAN SURGICAL ASSOCIATION.

Twenty-fifth Annual Meeting, held at St. Louis, Mo., June 14, 15 and 16, 1904.

FIRST DAY—JUNE 14TH.

What are the Minimum Requirements for Aseptic Surgical Operations?—Dr. George H. Monks, of Boston, said that looseness of packing dressings in the autoclave was perhaps the most frequently neglected important factor in establishing asepsis. Unless dressings are given free space, steam sterilization is of no avail, no matter how long it may be continued,—if loose, however, fifteen minutes to a half hour at fifteen pounds will serve to kill spores as well as vegetated germs.

He suggested the introduction into operating rooms of the vacuum sweeping process, such as is used to rid sky-scrapers of their dirt. It is rapid and causes no dust. Air infection is a serious factor —more so than at present considered. Septic material should be disposed of by strictly antiseptic methods. In later years, the preparation of the skin of the operation area had undergone much simplification; he no longer considered the application of antiseptics to this part desirable or advantageous—simple scrubbing with soap and water followed by 70 per cent. alcohol serving the purpose better than prolonged soaking with antiseptics. This percentage of alcohol kills germs much more rapidly than any other. Gloves should always be worn by the operator. Ten minutes boiling of instruments is sufficient, but here, as in the case of the autoclave, unless the heat be allowed to come in actual contact with the germ-contaminated surface, the effort at sterilization is vain. To this end, therefore, it is necessary to unlock and take apart every instrument which is boiled. Caps and masks are, in the author's opinion, most important adjuncts. He showed a form of the latter used at Vienna and stated that it was probably the best of its kind. He advocated the free use of saline solution as a substitute for more irritating irrigations.

Dr. A. J. Ochsner, of Chicago, spoke of the need of a simpler direct system. Above all, he said, the chief must be uniform under all conditions. Changes must not be haphazard, but must in all details be governed by a spirit of reasonableness. Receiving credit for all successes, the chief must be responsible for all failures. Successful asepsis depends largely on patient and continued scrubbing with soap and water. The night before the hands of all who are to take part in operating are thoroughly scrubbed. As a rule, irrigation of the wound is avoided at the Augustana Hospital. As to catgut, he has settled upon a form of iodoformized gut that has worked very satisfactorily. Careful observations at this institution led him long ago to conclude that air infection could be discounted to a very large degree; contact infection being by all odds the most common form of wound soiling. The hands are in most cases the agents of infection.

Some Studies in Asepsis.—Dr. Charles Harrington, of Boston, said that in an average operating room one hundred and twenty colonies to the square inch might be expected to deposit in an hour. It has often been said that sweat is infection. He has tried again and again to prove this, but has failed. It is apparently sterile. Saliva, on the contrary, is a most potent cause and source of infection. This is expelled chiefly by persons uttering the consonants d, k, p and t. Streptococci and staphylococci are the germs most frequently expelled in the saliva. As many as 4,375 having been counted in a single droplet of expelled saliva.

Fractional Sterilization.—For culture medium preparation this process is necessary, but for pathogenic sterilization it is useless. All such spores are killed in ten minutes if absolute contact of steam to exposed materials is ensured in the autoclave. Sporulation fails in the absence of suitable temperature and of water, therefore, if the fractional method were necessary, a special technic between the periods of exposure to heat would be necessary.

Hand Sterilization.—Potassium permanganate-oxalic acid method has long outlived its usefulness. It simply causes an oxidation of organic products, but that this is absolutely valueless may well be shown both by the fact that the process may be repeated almost indefinitely—the degree of blackening barely diminishing—as well as by actual bacteriological examination of the hands. The black coating, formerly considered so valuable an indicator of work well done, has been positively shown to be a most effectual bar to the accomplishment of sterilization. The author detailed his experiments with all the well-known solutions and showed how faulty is their action and how erroneous is the judgment of him who places faith in them. The free mercury ions are the factors of first importance in killing germs and their spores. Hydrochloric acid will increase the number and activity of these ions, but it is too irritating to use in practice.

Dr. De Forest Willard said that the value to the general surgeon of the laboratory findings, presented by Dr. Harrington, could not be adequately estimated. He agreed with Dr. Ochsner in that permanent assistants are a desideratum, but pointed out the fact that such a plan, if universally adopted, would seriously curtail the educational usefulness of all hospitals. The young generation must be taught, and this can be done only by a rotation of service. Operating rooms should be places near the roof; we are coming back to the old idea of Lister who placed such store on the importance of air infection.

Dr. C. B. Nancrede, of Ann Arbor, Mich., said that he had watched the development of asepsis for thirty-six years. Old ideas and old experiments were repeated again and again. The fact that inhibition of a germ is most difficult to distinguish from its death has led to many errors. Tissue resistance, that immeasurable something, is likewise a most potent factor. He places a five-minute sand-glass, commonly used by housewives to boil eggs, before each assistant and nurse, so as to ensure adequate scrubbing. The scrub until "hard boiled"

is reached. Last winter he caused 213 cultures to be taken from the hands of his operating staff with a result that seven grew. This showed 97 per cent. of sterility—this was reached by Weir's method of soda and chloride of lime.

A Chemical Study of Forty-one Operated Cases of Ulcer of the Duodenum.—Dr. W. J. Mayo and Dr. Christopher Graham, of Rochester, Minn., presented this paper. Dr. Mayo said that the striking fact elicited by this study was the proof it afforded of the frequency of the coexistence of duodenal and gastric ulcer. In 53⅓ per cent. of his patients the stomach was involved. Moynihan reports 23 per cent. Most duodenal ulcers are of the cicatricial type, as evidenced by the presence of broad adhesions walling off areas of chronic perforation. Duodenal ulcer is much more common than generally supposed. Its development is favored by the position of the organ as well as by other factors. The ulcer occurs, as a rule, within the first two inches of the gut. So frequent is the lesion as a complicating factor in gastric ulcer and in gall-bladder disease that the author recommends the use of an incision situated well to the right of the median line so that the duodenum, which is involved in at least one-half of such cases, may be explored and, if necessary, receive treatment.

Posterior Gastro-Enterostomy the Operation of Choice.—The anterior operation has been superseded at Rochester by the somewhat more prolonged but more satisfactory posterior. Even if this operation be employed, there is still a marked disposition to closure of the opening as a result of the increased pyloric lumen. Food is forced through the pylorus by the muscular action of the stomach. This mechanically dilates the part. Add to this the shrinkage of the inflamed walls, which begins as soon as they are given relative rest by the establishment of the artificial opening, and it is easy to see that it cannot be long, in most cases, before the pyloric opening which, at the time of the operation, may have been tightly sealed, becomes patent.

Classification.—Duodenal ulcers may be grouped under five heads: (1) Those occurring in conjunction with gastric ulcer; (2) with hepatic lesions, particularly gall-stone; (3) a large class in which acute perforation may take place; (4) one in which hemorrhage may supervene and (5) a small class characterized by a freedom from hepatic or gastric involvement.

Dr. E. Willis Andrews, of Chicago, cited a case in which he had employed the McGraw ligature to create a gastro-enterostomy. The patient died a year after the operation and the contraction of the opening proved the truth of Dr. Mayo's observations.

Dr. J. B. Murphy, of Chicago, said that Dr. Mayo had convincingly shown the frequency of duodenal ulcer. It produced, unlike its proto-type in the stomach, either absolutely no symptoms or, at best, the most vague evidence of its existence. The majority would for a long time have to be diagnosed upon the operating table.

Dr. Mayo, in closing, said that the so-called Robson ulcer of the stomach and of the duodenum were similar lesions and were too often confounded with gall-bladder disease. Eliminating the medical ulcers, duodenal ulceration is probably as common as gastric. Because of the difficulty of establishing a gastro-enterostomy which shall remain permanently patent and because of the danger of leaving a cicatrized base for possible future malignant degeneration, excision of the ulcer, rather than gastro-enterostomy, secured the operation of choice.

Seven Cases of Complete Removal of the Shaft of the Tibia, with Restoration of the Bone.—Dr. George Ben Johnston, of Richmond, Va., said that the striking factor elicited by a study of these cases was the differing degree of the virulence of the infection. He exhibited a complete series of photographs and radiograms which illustrated most convincingly what can be done by patience and skill in this department of conservative surgery. His illustrations showed how easy it became, in skilled hands, to actually mold the new bone to whatsoever form desired.

Dr. Willard said that under the reproachful term "rheumatism" most of the unfortunate childen suffering from osteomyelitis were condemned to suffer the agonies of tissue destruction until it was too late to save the bone. Operation should be done within the first forty-eight hours.

Dr. A. J. Ochsner advanced the proposition that the dead bone, which is usually removed from these, will in a large proportion of cases regenerate if kept clean and left *in situ*. He recalled one operation, four years ago, in which the fragment, consisting of almost the entire tibia, had grown fast and had given no trouble to date. He, therefore, advocated free incisions in these cases without bone resection. If the dead part does not grow fast it at least serves for a splint.

Second Day—June 15th.

Causes of Death after Abdominal Section.—Dr. Maurice H. Richardson, of Boston, said that to every surgeon of wide experience came occasionally but surely rare and unavoidable calamities which terminated in unexpected, unlooked-for death.

Pulmonary Embolism.—This condition and its evil associate, femoral thrombosis, are as inexplicable as they are to be dreaded. Neither has any bearing on wound infection, in fact, it is well known that each is more apt to occur in the course of an uneventful convalescence than otherwise. Have phlebitis and pulmonic embolism a common origin? Each, so far as can be determined at any rate, is aseptic, and each occurs typically after the most successful operations. It is possible that changes in the blood occur which are not evidenced by known methods of examining this tissue. But why should thrombosis of the left femoral occur so frequently after operations on the right side? That the two conditions are associated with each other and with some form of anemia is to be suspected, at least from the frequency of their occurrence in patients who have suffered prolonged hemorrhage.

Suppression of Urine.—This postoperative complication in patients whose kidneys are normal is not common and is rarely fatal; nevertheless it does occur with sufficient frequency to justify comment on our inability to prognosticate or to treat it. When it proves fatal it is probably a certain sign of preexisting renal disease which had been overlooked by the surgeon. Ether is usually not responsible.

Prolonged Capillary Hemorrhage.—This appalling sequel is most frequently seen after operations on the gall-bladder or its tracts. Blood-stained dressings persisting for some days beyond the usual has come to the author to suggest with painful certainty —death. In closing he said, that it was due the public to remind them that there yet lurked definite and uncontrollable dangers in the course of every operation of any import—as yet unhappily far be-

yond the reach or even the recognition of the surgeon.

Dr. L. S. McMurtry, of Louisville, spoke of the need of eliminating the baneful term "death from anesthetic," since in many cases autopsy, properly conducted, would show the definite cause of death to have been pulmonic embolism or some similar definite lesion. The laity should be taught that all operations are essentially not simple and uniformly successful. This has been the creed they have been taught and the altar at which they have been brought to worship in the recent years of marvelous surgical predominance and success. More time taken in the preparation of all except emergency cases would save many lives.

Dr. Robert Abbe, of New York, said that Keen had long ago called attention to the fact that the frequency of phlebitis on the left side was to be explained by the anatomical relation of the left vein. Most cases of left-sided phlebitis are mechanical in origin—representing a local stagnation of the venous current.

Dr. C. B. Nancrede said that he did not share with Dr. Richardson his dread of capillary hemorrhage. One case, he recalled, was operated on for jaundice and bled in this manner for five weeks without fatal termination.

Dr. W. J. Mayo said that in his experience phlebitis occurred in two per cent. of abdominal cases. Many are so slight as not to give any symptoms. One per cent. present the typical symptoms, the rest have only a little stiffness and pain. He had recently seen two cases of undoubted pulmonary hemorrhage recover and he had made the interesting observation that in each there was undoubted cardiac disease. A good-sized leak or a sudden break in compensation saves the heart until a readjustment of the circulation can be established. Each of the patients, he cited, had phlebitis subsequently.

Papillary Tumors of the Ovary.—Professor Samuel Pozzi, of Paris, France, said that a great number of women had been sacrificed to the popular, widespread belief that these forms of new growths are invariably to be considered malignant. It is true that if left alone they are very apt ultimately to undergo malignant degeneration, but this can occur only as a result of faulty treatment. The characteristic evidences of these cystopapillomatous growths is ascites and evidence of vegetations spread upon the omentum and general peritoneum. When, upon abdominal section, such vegetations are discovered and are shown to be the grafts of an ovarian papillocystoma, operation, far from being negated, is most urgently indicated. The author cited a patient upon whom he had operated in 1878, who lived without recurrence for twenty years. There is, pathologically, a very wide distinction between the grafting process which these tumors undergo and the well-known metastatic distribution of carcinomata and sarcomata by the lymphatics and the blood channels. Furthermore, and as furthering the plea for removal of these growths, even if apparently malignant, it is a well-established fact that malignancy, when it does subvene in these growths, usually for long periods, remains so strictly localized as to permit of its entire removal. Gross evidence of malignancy should not, therefore, contraindicate a hopeful postoperative prognosis. The patient should be safeguarded, if necessary, by repeated laparotomies, the need for these being, as a rule, determined by returning ascites.

The adnexa should be removed on both sides in women of over forty years of age even if one side alone be involved. Hysterectomy is immediately indicated if there be the least suspicion of malignancy. Drainage is unnecessary if ascites be absent, and if present, it is the author's custom to employ a glass tube with gauze for a few days only. It does no harm and often seems to act as a deterrent of malignant development.

Dr. Dudley P. Allen, of Cleveland, said that the danger of malignancy in these cases had been grossly overestimated and that every particle of available vegetation should be removed. He warmly congratulated Professor Pozzi on his brilliant paper and thanked him for bringing before the association with such force and earnestness a topic of so wide interest and importance. He cited a case which in all details supported what Professor Pozzi had said—auto-infection by medullary carcinoma having been induced from a papillomatous cyst.

Dr. J. E. Moore, of Minneapolis, said he had been favorably impressed by Professor Pozzi's paper. The question of the malignancy of papillomatous ovarian cysts had long been a subject of open discussion and he was glad to feel that it had at length been closed by so able a clinician.

Dr. Wm. B. Coley, of New York, reported a case of papillomatous cystoma which had been mistaken for a hernia. To his knowledge the patient, after resection, lived for seven years in perfect health.

Dr. A. J. Ochsner considered Professor Pozzi's conclusions to be epoch-making. Very careful distinction should be made between metastasis and the grafting of a papilloma. He considered the removal of the uterus a desideratum, because of the danger of broad ligament involvement.

Dr. L. L. McArthur, of Chicago, said that he had often found tuberculous germs in the apices of the papillomata.

Professor Pozzi, in closing, said that his remarks had been confined strictly to papillocystomata of the uterus and ovaries; they did not apply to such growths of the bladder and rectum. As to hysterectomy, he believed that every woman should be given an opportunity to bear children and that surgeons should be as conservative as possible.

He cited the case of a woman in whom he had resected all but a small portion of one ovary who had had her child and in whom a secondary operation was done shortly after delivery. As to the cause of the condition, whether tuberculous, as had been suggested by Dr. McArthur, or due to chronic irritation, such as is caused by chronic metritis, he was unable to say anything definite.

Anchylosis treated by Arthroplasty.—Dr. J. B. Murphy, of Chicago, presented the case of a young man in whom he had succeeded in reproducing a well functionating hip-joint. He exhibited photographs and radiograms of the new joint which showed the result very clearly. He said that there were two important questions to be answered, viz., "Can bony anchylosis be prevented?" "Can a normal joint be reproduced?" Three types of anchylosis have to be considered, the peri-articular, the capsular and the bony. Hygromata, as is well known, are often produced in the case of tumors and others who characteristically suffer from enlarged bursæ, the result of chronic irritation. The aim of him who would remake a joint should be to produce such irritation upon such tissues. Experimentation had shown that hygromata can best be produced by subjecting fatty tissue to constant pressure. This principle has a great future in the treatment of certain

chronic joint affections; it seems specially suited to cases of adherent patellæ, in the elbow and in the hips.

(To Be Continued.)

AMERICAN GYNECOLOGICAL SOCIETY.

Twenty-ninth Annual Meeting, held in Boston, Mass., May 24, 25 and 26, 1904.

(Continued from Page 1101.)

Second Day—May 25th.

Primary Repair of Lacerations of the Cervix Uteri.—There was a symposium on this subject. Dr. Edward P. Davis, of Philadelphia, read the first paper. Experience in 53 cases had led to the following conclusions: When the patient was not infected and when the tissues had not been subjected to sufficient violence to threaten necrosis and laceration of the cervix, one-half inch or more in extent was present, primary closure had been followed in his experience with good results. These cases usually occurred in primiparæ where resistance in the soft part occasioned sufficient delay and fatigue to require delivery by forceps. They were also seen in cases of premature labor, whether spontaneous or induced, where the cervix was not physiologically softened for perfect dilatation. They were also found in paitents having spontaneous labor with very strong expulsive efforts, and with large children. Naturally those cases in which the mechanism of labor was abnormal through posterior rotation of the occiput, face presentation or breech presentation, predisposed to laceration of the cervix. While primary closure of laceration of the cervix was indicated in the conditions just described, certain conditions were necessary for its successful performance. These conditions were outlined. Dr. Davis then described the technic of the operation, and the after-treatment. The number of cases under observation was 53. In these, good union occurred in 45; fair union in 6; no union in 7, while infection developed in none. In 84.9 per cent. the operation was successful; in 11.3 per cent. it was moderately successful, and in 3.8 per cent. the operation failed. The percentage of infection was *nil*. He pointed out the objections which were commonly urged against this operation, after which he said that in appropriate cases in his experience immediate closure of the cervix had given no inconvenience to the mother, and had been followed by excellent results. The operation was not advised for those who do not practice obstetrics with good surgical technic, and who were not competent to operate on the genital tract.

The Practice of Cervix Suture on the Fifth Day After Delivery.—Dr. Robert L. Dickinson, of Brooklyn, said that no complicated or considerable perineal injury should be repaired at the close of labor, but three to five days later. This had an important bearing on lacerations of the cervix, as this was the ideal time to restore such injuries. The huge edema, the bruising, and the uncouth distortion of the vaginal portion just after delivery rendered identification of the parts that should be brought together impossible, and attempt to accurately coapt, guesswork. Therefore, whenever possible, the cervix should be sewed on the fifth day. The frozen sections of the puerperal weeks showed that then, and not until then, shrinkage had occurred. Bleeding no longer obscured the difference between flayed surface and torn structure. Then only were the surroundings of the operation, in the way of illumination, table, time, and a rested personnel possible. This applied particularly to private practice. The conditions under which the cervix should be repaired at the close of labor were: (1) Bleeding from a firmly contracted uterus, notwithstanding ergot, heat, holding, and tampon. Here there was a spurting artery. (2) When the cervix injuries were clean cuts, of known location, as after Dührssen incisions. (3) When, in the immediate repair of a moderate perineal injury, a tear of the cervix is found. The conditions under which the cervix should be repaired several days after labor were: (*a*) Exhaustion of patient, or surroundings and conditions which precluded careful work. (*b*) Extensive injuries, except when these persistently bled or had been cut by the surgeon. (*c*) When accompanied by complicated or considerable injuries to the pelvic floor. The author drew attention further to the alterations produced by granulation and contraction in these wounds when left alone, so that the scarred, swollen, everted, or cystic cervix months or years after injury gave uncertain indications for accurate restoration to the original condition.

General Considerations of Laceration of the Cervix Uteri.—Dr. J. M. Baldy, of Philadelphia, stated that as a matter of clinical fact, let the cervix uteri be torn deeply and if the parts were preserved from infection, the greater part of the tear would heal spontaneously, and the rest of it would remain perfectly healthy, as much so as would the lobe of the ear which had been torn through by the weight and drag of our great-grandmother's earrings. The lips would remain uninfiltrated of normal size and thickness, with no eversions and no erosion of the lining mucous membrane. In such a case there would be no untoward symptoms and no bad effects whatever. There was a tendency among obstetricians to repair these lacerations primarily. The objections to such practice were manifold, and he admitted a prejudice against it. These objections were pointed out. Whatever might be ideal surgery under the exigencies of actual practice, the treatment for recent lacerations of the cervix remained, and he believed would remain, rigid local cleanliness, excepting where there was sufficient hemorrhage to demand a ligature. Where noninfection could be insured, and where the torn lips were not unnecessarily disturbed, by the careless use of the nozzle of a syringe, spontaneous healing of these lacerations might be expected to a greater or less degree, and what tear remained, when nature was through with her work, would be of a healthy character, would give no future trouble, and would need no surgical interference. The symptoms of chronic lacerations of the cervix uteri were essentially local in their production and remained so in their manifestations. He had no sympathy with the views which attributed reflex symptoms to these lesions. In uncomplicated cases, where there simply existed a laceration of the cervix uteri, with everted and eroded lips, producing a constant leucorrhea and a feeling of weight and uneasiness in the pelvis and about the rectum, these so-called reflex symptoms did not exist. There was one belief prevalent which would warrant, nay demand, a repair of every lacerated cervix—the belief that lacerations of the cervix produced carcinoma. In this belief he took no part, and no one had to his knowledge as yet produced a single scientific fact which would uphold such a theory. In twenty years' work he had not seen a single case of cancer develop in a laceration of the cervix which he had refused to repair.

Intrapelvic Hematoma.—Dr. J. Whitridge Williams, of Baltimore, reported a case of intrapelvic hematoma following labor, and made some remarks on the treatment of incomplete rupture of the uterus.

Presidential Address.—Dr. Edward Reynolds, of Boston, in his Presidential Address, said, among other things, that the Society owed its preeminence along its chosen line less to the words than to the prolonged and daily labor of the eminent men who had composed it in

the past, and must owe its future to the lifework of the equally able men who were to fill its membership in the coming years. He said the use of the printed abstract published beforehand had of late become increasingly prominent in many societies, and in the British Medical Association this use of the abstract had reached its highest terms. It was seldom wise to adopt wholesale the regulations of other organizations. It was usually better to let changes follow a more gradual and natural evolution under the needs of the individual assembly, but the methods of the English association were worth a passing consideration. A Fellow of the British Medical Association who desired to present a paper at one of its meetings, must put it in the hands of the Secretary complete and in the form in which he desired its publication a number of weeks before the meeting, and the communication might be of any length he chose. A paid Secretary, a qualified and experienced medical author, then abstracted each paper in the form and length which he considered best fitted for its public delivery. This official then read the abstracts to the Society as they were called from the program. Such a reading inaugurated each discussion, and the member whose ideas had been thus succinctly set forth before his associates took part in the discussion and closed it. The ideas of individual members by this method were better and more intelligently presented to the Society than if they had read their complete papers. In this way the time of the Society was economized, full debate was encouraged, and the members had the advantage of publishing to the world papers in which their points were set forth at the fullest length and without time limitation.

Dr. Reynolds said that such a method was perhaps too far advanced for our present needs or possibilities, yet it had many advantages, and it seemed to him worth calling attention to as one toward which the Society might well advance. Would it not be wise to give this method, or a modification of it, a year's trial? In conclusion, he expressed his thanks for the kindly personal feeling which had actuated the Fellows when they elected him President, for which, and for the many personal pleasures which he had enjoyed in the Society, he was, and would always gladly remain, their willing debtor.

SYMPOSIUM ON INJURIES TO THE PERINEUM.

The Preventive Treatment of Pelvic Floor Lacerations.—Dr. J. Clifton Edgar, of New York, read the first paper. The most important part of the management of the second stage of labor was the prevention of pelvic floor lacerations, lacerations of the fourchette in primiparæ, and superficial tears about the vulvar orifice in both primipara and multipara often occurred, were often unavoidable, and usually readily healed with simple asepsis. Deep lacerations were avoidable in normal, ordinary cases of labor. The factors which tended directly or indirectly to produce pelvic floor lacerations were numerous, but for convenience he arranged these in three major classes. These were concisely stated as: (1) Too rapid expulsion of the fetus, so that tearing instead of stretching resulted. (2) Relative disproportion in size between the presenting part and the parturient outlet. (3) A faulty mechanism of labor, whereby the larger circumference of the head and shoulders than necessary passed through the parturient outlet. From an extended clinical experience, he could speak most enthusiastically of the preliminary digital stretching of the vulvar outlet in primiparæ, and especially in elderly primiparæ, as a prophylactic measure in perineal protection.

The author then discussed episiotomy, head delivery, and cleidotomy. Regarding shoulder delivery, the author firmly believed from years of careful clinical observation that the posterior shoulder was responsible for many instances of deep pelvic floor laceration. Furthermore, that moderate ruptures caused by the passage of the head were often increased and rendered serious by the subsequent passage of the posterior shoulder. He had been most successful with the following method of shoulder delivery, and either the lateral or dorsal posture of the patient could be used at will. This method was not new: (1) The delivery of the shoulders was delayed, if possible, until nearly complete rotation of the bisacromial diameter had taken place. (2) The fetal head was taken in the hand and gently raised or pushed, so as to bring the anterior shoulder well up behind the symphysis, thus giving the cervico-acromial diameter of the fetus at the outlet instead of the bisacromial. (3) The posterior shoulder was now allowed to pass out spontaneously and whenever possible manual extraction should be avoided, as this increased the risk of perineal rupture. (4) During the detention of the anterior shoulder behind the symphysis, the fetal hand of the opposite arm lying across the fetal chest would usually soon appear in the vulva. He had found that delivery might be safely assisted by slowly flexing this forearm and arm out through the vulva and thus delivering the posterior shoulder by slight traction on the posterior arm. (5) Should the foregoing be impracticable and delay in the expulsion of the posterior shoulder occur, he had found gentle traction upon the head, the fingers encircling the neck, to be preferable to traction with a finger in the axilla. (6) Should there be delay in the delivery of the anterior shoulder, after expulsion of the posterior, it was best remedied by making traction directly downward, with the hands placed on the sides of the head, taking care not to make too great pressure on the perineum.

Immediate Repair of Lacerations of the Perineum, with Special Reference to Placing the Sutures Before the Lacerations Occur.—Dr. Lapthorne Smith, of Montreal, spoke of the importance of closing up even small tears of the perineum, so as not to leave raw surfaces for septic absorption. It was important to close large tears so as to retain the function of the pelvic muscles. The best time to put in these stitches was just before the head pressed on the perineum, while the patient was anesthetized, and before the parts had lost their relative positions. With the left finger in the vagina and the thumb in the rectum, a large perineum needle on a handle was passed just under the vagina, threaded with silkworm gut; the two or three stitches hung loosely in a Pean forceps until the placenta had been delivered, when they were quickly tied, bringing the parts exactly together as they were before the tear.

Immediate Repair of Injuries of the Pelvic Floor.—Dr. Henry C. Coe, of New York, said that he had selected this topic in order to emphasize the fact that by careful attention to puerperal lesions at the time of their occurrence the patient could be spared much future trouble. He assumed that it was the usual practice of modern accoucheurs to repair injuries to the pelvic floor at once, but it was one thing to suture visible tears and another to repair deeper lesions. Even when perfect union of the lacerations was obtained, the occurrence of prolapsus, cystocele and rectocele months afterward proved that there had been some fault in the technic. The fact of the separation of the fascia and levatores ani muscles must be recognized as well as the superficial tear, especially after difficult instrumental deliveries. An illustrative case from the writer's practice was cited. The tendency of the accoucheur after a tedious instrumental case, in which both physician and patient were exhausted, was to spend as little time as possible in repairing lesions of the soft parts, trusting to aseptic technic to insure perfect healing. The writer was firmly of

the opinion that it paid to do the work thoroughly at the time, unless the patient's condition was such as to render delay advisable. He had had such good results from immediate operations that the intermediate did not appeal to him. In conclusion, he alluded to the fact that the modern accoucheur must be a surgeon as well as an obstetrician. It was expected of him to leave the patient in as good condition as he found her, otherwise he properly laid himself open to criticism.

Uniformity in Pelvic and Cranial Measurements.—Dr. A. F. A. King, of Washington, D. C., read a paper on this subject, in which he reached the following conclusions: (1) That at present the measurements of the normal pelvis and fetal head are indefinite and unsettled, and must continue so to be so long as they are determined by our present methods of mensuration. (2) The chief purpose in obtaining the normal dimensions of these structures being for teaching and learning the normal mechanism of labor, it is proposed to adopt an ideal or hypothetical head and pelvis, upon the dimensions of which all authorities may agree. (3) In the adoption of such ideal structures, it is unnecessary and undesirable to define any measurement with exact precision—no fraction smaller than one-fourth of an inch, or half a centimeter (in the metric system) being required. (4) Race variation forms no real obstacle to the proposed plan, and other apparent difficulties can be overcome. Finally, should the proposition meet with approval, it is suggested that this Society take the initiative in bringing the matter in proper form before some forthcoming international medical congress for general adoption. Accordingly, a committee was appointed by the President to consider the matter of uniformity in pelvic and cranial measurements, and report at the next annual meeting.

SYMPOSIUM ON NON-OPERATIVE LOCAL TREATMENT IN GYNECOLOGY.

Dr. Willis E. Ford, of Utica, N. Y., in reading the first paper on this subject, said that no one would deny that greater good had come from surgical treatment of diseases peculiar to women than was ever dreamed of by the early gynecologists who did not operate. No comparison of results could be made. He did not think it was true, however, that the specialty ought to become purely surgical. Pathology learned by pelvic and abdominal surgery ought to be clearer and better than was ever discovered post mortem. It was fair to assume that men who did this work had a better idea of the natural history, progress, and dangers of these diseases than those who did not operate; and that, therefore, the early treatment ought to be in the hands of men who were also doing surgical work. The nervous habit could not be cured by surgical procedure. What was commonly called neurasthenia was not a disease, but an established habit, possible only to those who had from birth an unstable or weak nervous constitution. Before the mental symptoms began was the time to prevent neurasthenics from becoming permanent invalids. That the nervous habit could not be cured by surgery had been proven by the fact that the removal of diseased ovaries, and such like operations on epileptic women, had not cured the epilepsy or neurasthenia. The argument, therefore, was that in those ailments that tended to disturb the emotions, especially those of the reproductive organs of men or women, the serious thing was not the pain experienced, but the permanent invalidism which was brought about by the protracted local sensations that in time disturbed the mental equilibrium and brought about the invalid habit. These local irritations ought to be treated by skilled gynecologists, and not allowed to develop either the mental or physical ailments which were so common a result. These arguments were enough to make the profession to revive its interest in non-operative procedures. Recent displacements, especially in young people, and acute infections were mentioned as demanding non-surgical care early, if one wished to avoid the more serious ailments, and especially the most serious of all, the mental disorder called neurasthenia.

The Value of Non-operative Local Treatment in Pelvic Disorders.—Dr. Walter P. Manton, of Detroit, Mich., said that the ignorance of proper methods, together with the fascinations of operative measures, had brought the local treatment of pelvic disease into disrepute. Three of the factors, which among others at the present time were largely responsible for the neglect of medical gynecology, were: (1) The average physician's lack of knowledge in the accurate diagnosis and local treatment of pelvic disease. (2) The allurements and fascinations of surgery, and (3) competition in the field of practice. While it was true that no amount of instruction could impart a *tactus eruditus*, still anyone could acquire a knowledge of the primary principles underlying the correct interpretation of gynecic ailments, if opportunity was offered for the practical examination of patients under competent direction. In ignoring the benefits to be derived from medicine, he was convinced that surgery had gone too far and that it had overshot the mark, but that the present tendency to operative measures in all conditions affecting the pelvic organs could not be ascribed so much to the good which surgery, rightly directed, was capable of accomplishing as to other elements which had entered into the case was also evident. In the best of hands the results from local treatment in pelvic diseases were frequently slow in manifesting themselves, and discouragements were often met with, but in suitable cases persistent effort would ultimately attain the desired end. The objects of local treatment were the relief of pain and irritation, often of a reflex nature; the allaying of congestion and inflammation; the absorption of the products of inflammation, and the reposition of displaced organs. In the regulation of the uterine functions, in congestions and mild inflammations of that organ and surrounding parts, and in displacements of the uterus, with and without adhesions, the application of proper local treatment was of signal value; while in prolapse of the tubes and ovaries, even in the presence of extensive adhesions, but without ascertainable morbid changes in the organs themselves, vaginal tamponade offered the simplest and most efficient means of reposition and cure.

Treatment Preparatory to Operation.—Dr. Henry C. Coe, of New York, introduced his remarks with the statement that while his early training had led him to believe that such treatment was practically indispensable in cases of so-called "cellulitis," subsequent experience had convinced him that his notion was not in accordance with pathology or common sense. He had expressed skepticism in this subject as long ago as 1886, when he read a paper on the "Exaggerated Importance of Minor Pelvic Inflammation," and subsequent experience had only served to confirm his opinion that old pelvic exudates and adhesions were not *per se* a contraindication to operations on the uterus. Modern aseptic technic was a sufficient safeguard against danger from this source. The reader contrasted the old practice of keeping a patient in a hospital for several months, with the preparatory treatment between each minor operation, with the present plan of performing combined operation at one séance, and sending out in three or four weeks. He questioned the actual value of the hot vaginal douche, local applications to the vaginal fornix, treatment of the ectopic cervix, etc., previous to trachelorrhaphy, since the diseased tissue would all be removed at once by amputation. At the same time, he admitted the

remarkable results often observed as regards the absorption of extensive pelvic exudates. Acute and subacute inflammations in and around the adnexa formed the real contraindication to operation, and doubtless surgeons were not always as careful as those of the former more conservative generation in selecting their cases. Competition and the rush of modern life were responsible for some ill-advised operations, minor, as well as major. In regard to major operations, the author thought that (excluding pus cases) general preparatory treatment of the patient was rather more important than local. He believed, however, that the admirable results obtained by the pioneers in the treatment of vesicovaginal fistulæ were due to careful preparatory treatment, such as the divisions of cicatrices, stretching of the vagina, etc. Fortunately we were seldom called upon to handle such complicated cases as those described by Sims, Emmet, and Bozeman. With all our improvements in technic, we had not yet outgrown all the wisdom of our old teachers.

The Value of Post-operative Local Treatment.—Dr. J. Riddle Goffe, of New York, said the experience of all observers was that local treatment relieved congestion, pain and discomfort, inaugurated, hastened and accomplished the absorption of edema, plastic exudate, adhesions, and pseudohypertrophy. If it would relieve these conditions, how much more certainly would it prevent them? It had been found serviceable in preventing the deposit of plastic exudate and the reformation of adhesions in cases in which these were present at the time of operation. It was especially valuable in cases subjected to vaginal section for the relief of sterility. The author reported several instructive cases to substantiate the points made in his paper.

The Implantation of the Human Ovum in the Uterus.—Dr. Chas. Sedgwick Minot, of Boston, discussed this subject by request. He stated that the human ovum produced upon its exterior during its earliest stages of development a thick layer of cells, the trophoblast. The function of the trophoblast was to corrode away a portion of the mucous membrane of the uterus, making a cavity in which the ovum lodged itself. The trophoblast thereupon underwent a hypertrophic degeneration, such as to produce a series of irregular spaces, which persisted and became the intervillous spaces of the placenta. Papillary outgrowths of the chorionic mesoderm meanwhile penetrated the trophoblast, initiating the formation of the chorionic villi. The trophoblastic cells over each mesodermic outgrowth persisted in two layers, the inner cellular, and the outer syncytial. These two layers represented the first stage of the villus ectoderm. Similar observations had been made upon primates, and were compared with those upon the human subject. He compared briefly the method of implantation in man with that in other animals, to show that the trophoblast was of general occurrence, and that by destroying uterine tissues it inaugurated the formation of the true chorionic placenta.

Bathing During Menstrual Period.—Dr. J Clifton Edgar, of New York, said that in the consideration of this subject several questions suggested themselves, namely (1) the advisability of bathing of any description during the menstrual period, and if at all, to what extent; (2) the use of the bath in dysmenorrhea; (3) the use of Nauheim or other chemical baths or hydriatic procedures; (4) the risk of infection of the endometrium in intramenstrual tub-bathing; (5) the influence of modern athletics on women, lessening the risk, if any, of intramenstrual bathing. These questions were submitted to the members of the Society, from whom he had received 122 acknowledgments. From the replies received, and the literature on the subject, he drew the following conclusions: (1) All forms of bathing during the menstrual period are largely a matter of habit, and usually can be acquired by cautious and gentle progression, but not for every woman does this hold good, and surf bathing, where the body surface remains chilled for some time, should always be excepted. (2) A daily tepid sponge bath (85° to 92° F.) during the menstrual period is not only a harmless proceeding, but is demanded by the rules of hygiene. (3) In the majority of, if not all, women, tepid (85° to 92° F.) sponge bathing after the establishment of the menstrual flow, namely, second or third day, is a perfectly safe practice. (4) Furthermore, in most women the habit of using the tepid shower or tub bath after the first day or two of the flow can with safety be acquired."

The Streptococcus in Gynecological Surgery.—Dr. Hunter Robb, of Cleveland, Ohio, stated that in order to arrive at some definite conclusions with reference to the *Streptococcus pyogenes* as a cause of death in his work, he had made an analysis of all his cases in which this organism had been found during the past six years. It was shown from observations that quite a large number of his patients died, and several were unimproved. It was also noticed that in the great majority of cases in which this organism was met with, there was a previous history of infection following labor, or an induced criminal abortion. In the past six years he had had 137 cases of abortion (including a few cases of labor) in which it was necessary to carry out some form of treatment. Of this number, 104, or 75.9 per cent., recovered; 17 or 12.4 per cent. were improved; 1 or .8 per cent. was unimproved, and 15 or 10.9 per cent. died. In 16 of the 137 cases the streptococcus was found. The total number of all his cases in which the streptococcus was found was 40, consequently those in which this organism was found following an abortion or labor formed 40 per cent. of the total number of streptococcus cases from every source. Of these 16 patients (streptococcus cases) following abortion or labor, 4 or 25 per cent. recovered; 3 or 18.75 per cent. were improved; 9 or 56.25 per cent. died. In the whole 40 cases from every source, in which the streptococcus was found, the results were as follows: Recovered, 20 or 50 per cent.; improved, 6 or 15 per cent.; deaths, 14 or 35 per cent. The streptococcus was found in the following combinations given in order of frequency: (1) *Streptococcus* alone; (2) *Streptococcus* and *Staphylococcus pyogenes aureus;* (3) *Streptococcus, staphylococcus aureus,* and *Bacillus coli communis.* In all these cases, except three, in which they were obtained from the vagina, the organisms were obtained from the uterus, the adnexa, the cul-de-sac, or from several of these situations. In other words, they were proved to be present in places which were admittedly not their normal habitat. In the past five years he had had 724 abdominal sections, with a total number of 32 deaths, or 4.43 per cent. In 7, or 21.9 per cent. of them, the *Streptococcus pyogenes* was demonstrated. In all there were 19 cases of abdominal operations in which the *streptococcus* was found. Of this number, 12 recovered, or 63.2 per cent., and 7 died, a mortality of 36.8 per cent.

The Nature of the Indications for Operation for Fibroid Tumors of the Uterus.—Dr. Chas. P. Noble, of Philadelphia, presented a table of the degenerations and complications in a series of 1,188 cases of fibroid tumors operated upon by Martin, Noble, Cullingworth, Frederick, Scharlieb, and in series reported by Hunter and MacDonald. Especial attention was called to the relative frequency of adenocarcinoma of the uterus as compared with epithelioma of the cervix. The deduction drawn from this fact was that fibroid tumors were a direct predisposing cause of cancer of the cervix. A

careful consideration of the facts presented in the table, said the author, should convince anyone with an open mind that the classical teachings concerning fibroid tumors were erroneous. This teaching was that fibroid tumors of the uterus were benign growths, which usually produced but few symptoms, and which after the menopause underwent retrogressive changes, becoming smaller or disappearing; that the chief danger of fibroid tumors consisted in the fact that at times they caused hemorrhage from the uterus, and that rarely they caused trouble because of their size or because of pressure on adjacent viscera. An analysis of the 1,188 cases showed that because of the degenerations in the tumors, about 16 per cent. of the women would have died without operation; about 18 per cent. would have died from the complications present. In addition, it was well known that a certain percentage would have died from intercurrent diseases brought about by the chronic anemia present in many of these cases, and by injurious pressure from the tumors upon the alimentary canal and urinary organs. In brief, at least one-third of the women having fibroid tumors, as shown by the author's table, would have died had they not been submitted to radial operative procedures.

The Treatment of Gonorrhea.—Dr. Henry T. Byford, of Chicago, said there was dissatisfaction with prevalent methods of treating this disease. The desideratum was a local remedy that would rapidly destroy or remove the germs without injuring the protective epithelium, and a method of application that could be used by the patient which would not carry the germs to a deeper portion of the genito-urinary tract. He advocated prolonged irrigations with hot water as a basis, and spoke of frequent injections of hot water as a substitute for prolonged irrigations. He detailed his experience with urethritis in the male, and referred to hydrogen dioxide and unirritating germicidal solutions as substitutes for plain water injections, and gave their application to gonorrhea in the female. The advantages of this treatment, when used early, were summarized by him as follows: (1) It prevents the spread of the disease to adjacent parts; (2) it does not injure the epithelial covering, and it tends to limit the infection to the superficial areas; (3) it removes more germs and pus cells than either astringents or disinfectants can destroy; (4) it acts in the same way as constant irrigation, both in aborting and arresting the progress of the infection; (5) it can be used more frequently than astringents or strong germicides, so that the parts can practically be kept free from pus and germs all of the time, while the method of using germicides or astringents three or four time daily allows the germs and pus to accumulate and spread between injections. (6) In the male, and possibly in the female, peroxide injections may be substituted when the time and the facilities for the hot water treatment cannot be had. When the discharge has become scanty and the injections cannot readily be used so frequently, a non-irritating solution of a silver salt can follow each hot water or peroxide treatment. (7) It may be used in connection with alkaline injections for the dissolving of germs and culture material not eliminated by the douches. (8) It does no harm. It can be combined with the internal or local medication when it becomes impossible to carry it out with the necessary time-consuming detail. It exemplifies the superiority of asepsis to antisepsis.

Dr. Philander A. Harris, of Paterson, N. J., exhibited and described a new uterine obstetrical dilator and illustrated its practical features.

Niagara Falls, N. Y., was selected as the place for holding the next annual meeting, in May, 1905.

THE AMERICAN MEDICAL ASSOCIATION.

Fifty-fifth Annual Meeting, held at Atlantic City, N. J., June 7 to 10, 1904.

SECTION ON NERVOUS AND MENTAL DISEASES.

Second Day—June 8th—(*Continued*).

(Continued from Page 1232.)

Treatment of Aphasia by Training with Some Remarks on the Re-education of the Adult Brain.—Dr. Charles K. Mills, of Philadelphia, said that the cerebral zone of speech, the areas and centers for concrete memories and abstract concepts, their relation to cerebral education, the various psychic centres and their subdivision were referred to in detail, after which the author considered the varieties of aphasia and the various methods of training the patient, including the repetition of words, letters and phrases, Wyllie's psychologic alphabet, grammatical training and the relation of writing to speech, followed by a résumé of his personal views in regard to a motor graphic center. This was followed by an exhibition of two cases, the first of which was a total motor aphasic, and in addition thereto had Jacksonian epilepsy, so that he could only say his own name, the diagnosis being lesion involving the third frontal convolution and adjoining region, which under a careful system of training had greatly improved. The other case was that of a man about forty years of age, who about seven months ago had an epileptiform attack followed by aphasic symptoms, from which he partially recovered, and later had an intensification of the attack at which time he was almost completely word, letter and number blind; this case has also shown considerable improvement under treatment. He stated that in his opinion the sensory aphasics improved most rapidly.

Dr. T. H. Weisenburg read a résumé of the literature on this subject.

Dr. Charles W. Burr, of Philadelphia, believed that the method to be pursued should be the same as is used in the education of children, such as showing them an object, calling the object by a certain name, writing down the name, and letting them draw a picture of it. He did not approve of the system of having them repeat monosyllables. As so many of the cases are due to specific disease, he felt unless syphilis could be excluded, it would be difficult to say just how much of the improvement was due to training and how much to the absorption of the exudates due to the toxins of the specific disease.

Dr. W. G. Spiller, of Philadelphia, considered that there are four elements bearing particularly upon the prognosis: (1) Age; (2) nature of the lesion; (3) extent of the lesion, and (4) intelligence of the patient. Traumatic lesions, he believed, were more hopeful than those produced by hemorrhage into the brain, reporting two cases, due to trauma, one resulting in word deafness, in which by operation a large cyst was removed from the temporal lobe on the left side, and the man by his own efforts recovered a great deal from his previous hopeless condition.

Dr. Punton, of Kansas City, Mo., referred to the scarcity of literature on this subject, and also raised the question as to whether the efforts put forth by the patient would have a tendency to bring on a second attack, in those cases due to embolism and thrombosis.

Dr. F. W. Langdon, of Cincinnati, Ohio, felt that possibly the entire improvement could not be attributed to any one factor, either education, medication or the action of nature. He then referred to the fact that the third frontal convolution was not a motor speech centre, but rather a language construction centre, and that the real motor centre is the lower Rolandic region. He did not, however, believe that grammar had anything

to do with the acquirement or reacquirement of language by a patient suffering from motor aphasia.

Dr. W. J. Herdman, of Ann Arbor, Mich., felt that the degree of recovery depended upon the capacity remaining after the organic disease, traumatism, etc. He believed that if there was any capacity remaining it was for the nouns and verbs or main parts of a sentence and that the adjectives, adverbs, prepositions, etc., must be added by education.

Dr. Charles K. Mills, in closing, stated that the education of an aphasic could not be exactly the same as was indicated for a child, for the reason that he had an advantage over the child, in that his brain was once thoroughly organized, and a disadvantage in the fact that the child in its education started out with a potential mechanism of speech in the cerebrum, unattacked by disease. He also reviewed the various form of lesions causing the condition and the prognosis in the different cases.

Tuberculosis of the Nervous System.—Dr. D. J. McCarthy, of Philadelphia, gave a résumé of the work done at the Phipps Institute, and the results of a study of 78 autopsies and 126 cases clinically considered. He considered, first, the organic lesions and their various subdivisions, and second, functional disorders, due to either toxins generated by the tuberculous process or to mixed infection, the clinical and pathological findings being set forth in detail.

Dr. David I. Wolfstein referred to tuberculosis as a cause for meningeal encephalitis, and believed that not only did tuberculosis produce the nodular lesions, but also a more diffused form of softening, believing that the mental disturbance depended largely upon the extensiveness of this diffusion.

Dr. Spiller referred to a case which had been diagnosed as brain tumor, and for which an operation was done, but which proved tuberculosis of the nervous system.

Dr. D. J. McCarthy, in closing, remarked the frequency with which tuberculosis extends into the meninges and produces hemorrhagic encephalitis.

Facial Paralysis, Possibly Due to La Grippe.—Dr. F. W. Langdon, of Cincinnati, reported the history of a patient, a male teacher, fifty-one years of age, married and in good health. The attack occurred after a journey of fifty miles, prior to which he had been suffering from occipital headache for five weeks. No cardiac disease or syphilis was present. The symptoms began with logophthalmos, and three days later there was inability to close the left eye, which afterwards extended to both eyes, and during the course of the attack there were slight dysphasia, marked dysesthesia, blurred speech, and defects in the taste. The knee-jerks were absent and the plantar reflexes were flexor in type and active. There was bilateral facial paralysis and the response of the muscles to faradism and galvanism was sluggish.

Dr. T. H. Weisenburg reported three cases of bilateral facial paralysis, one of which gave a history of disease in the male members of the family for two prior generations.

Dr. Hugh T. Patrick, of Chicago, reported a case of double facial paralysis occurring in a child in which the electric reactions were not the ordinary reactions of degeneration, the eye muscles are not involved, nor are the muscles of the extremities to any great extent, but there are general lassitude, weakness and general fatigue, in addition to the facial paralysis, which case he was rather inclined to diagnose as myesthenia gravis.

Dr. Coulter, of Omaha, Neb., reported a case of unilateral facial palsy occurring in a physician following la grippe. The physician realizing that he was contracting the la grippe had driven all day in doing his work, resulting in this condition, the knee jerks were absent; there was a great deal of sweating, and both plantar reflexes were flexor in type.

Dr. Albert E. Sterne, of Indianapolis, Ind., referred to the case of a man who was thrown from a wagon striking on the back of the head a little to the right side, causing deafness in the left ear, paralysis of the left half of the face and loss of sensation in the right half of the body, in which case twenty years after under careful systematic treatment, the use of the facial muscles was recovered to a considerable degree, and the hearing and sensations on the right half of the body were restored to normal. Another case reported was that of a man who was stricken suddenly with symptoms exactly similar to poliomyelitis; later wasting of the muscles, which were paralyzed, and degeneration, which still exists to a large extent in the man's trunk and both halves of the face.

Clinicopathologic Study of Hemiplegia with a Microscopical Examination in Eleven Cases.—Dr. T. H. Weisenburg, of Philadelphia, gave a clinical report of the study of 150 cases of hemiplegia with especial attention to heredity, prehemiplegic and post hemiplegic pain, atrophy of the muscles of the paralyzed side, and the respiratory movements and trophic disturbances on the paralyzed side. In the pathological report particular attention was directed to the primary seat of the lesion, the degree of degeneration in the cerebral peduncle, the relative amount of degeneration in the direct and crossed pyramidal tracts with reference to the findings of Marie, Guillain and others, the state of the nerve cells of the anterior horns, and the conditions of the nerves and muscles on the paralyzed side.

Dr. Guy Hinsdale, of Hot Springs, Va., stated that he had frequently observed yawning accompanied by movement of the paralyzed arm or leg in a number of cases of hemiplegia, which, while he supposed was to be explained on the ground that it was a reflex condition did not have the characteristic quick movement of the knee jerk and other reflexes.

Dr. Hugh T. Patrick, of Chicago, Ill., cited the Jacksonian theory in explanation of the increase in respiration on the paralyzed side, which is that increased action of the muscles of the extremities on one side increases the action of the trunk muscles on the other side, which would therefore cause the weakness of the trunk muscles on the opposite from the paralysis.

Dr. Theodore Diller, of Pittsburg, Pa., believed that the sensory phenomena were present in many diseases which were attributed to pure motor disturbances, citing as instances thereof paralysis agitans and Landry's paralysis.

Dr. David I. Wolfstein, of Cincinnati, Ohio, reported two cases which had come under his observation in which the Babinski sign was present within one hour after the onset of the attack, and remarked upon the diagnostic value thereof when present early.

Dr. Coulter, of Omaha, Neb., reported a case of fracture of the skull, followed by coma and hemorrhage from both ears, in which the Babinski reflex was present within three hours after the accident.

Dr. Frank P. Norbury, Jacksonville, Ill., spoke of the hereditary character of the disease, and repoted an instance in which a physician, his father and grandfather had all died thereof.

Dr. Albert E. Sterne, Indianapolis, Ind., referred to the rise of temperature which is frequently present in the early cases.

Dr. A. C. Brush, Brooklyn, also discussed this paper, and Dr. Brainard reported the pathological results of autopsies on two cases of hemiplegia, the one occurring in a young woman during the menstrual period,

in which there was no cardiac lesion present, and in which he suggested the source of the clot might have been from the endometrium; the other occurring in a woman of about sixty years. In regard to the hereditary tendency, he reported the case of a man dying from this condition, whose male ancestry for three preceding generations had died from the same cause.

Dr. T. H. Weisenburg, in closing, stated that most of the cases were due to hemorrhage; that the paralysis was most marked in the distal ends of the extremities, and that in only 30 out of 109 cases was there any sensory disturbance. The Babinski reflex was observed in most cases within twenty-four hours; it was absent in three cases, and in two cases was present within twelve hours.

Two Cases of Congenital Deformity, Possibly Due to Intrauterine Disease of the Spinal Cord.—Dr. Charles W. Burr, of Philadelphia, reported these cases. The first patient was a man, fifty-five years of age, four feet tall. The head is practically normal; the skin is normal; no anesthesia; sensation preserved all over the body, the reflexes are present, and there was no clinical disturbance discovered; the legs and arms are deformed, and he is unable to walk on account of weakness of the muscles; the epiphyses of the bones are distinctly abnormal, and the skiagraph shows marked absence of lime salts in the bones of the hands. The other case was that of a male, aged twenty-three years, on which the shoulders, arms and forearms are deteriorated or never developed; the biceps-jerk is absent; there is no disease of the bones; there is very slight wasting in the left leg, which can only be detected by measurement. Several theories had been advanced as to the cause of the condition, among others, bilateral brachial palsy from birth, mal position in utero; but the author was rather inclined to believe that possibly the man had in utero disease of the anterior horns of the spinal cord.

Dr. F. X. Dercum, of Philadelphia, stated that he was quite familiar with the first case, and believed it to be due to disease of the bone, possibly associated with muscle and tendon disease. The other case he thought to be one of intrauterine poliomyelitis and could see no reason why the spinal cord should not yield to the toxic influences in utero, as well as in life.

Dr. B. Onuf, of Sonyea, N. Y., referred to a case in which there was a question as to whether the condition was due to congenital poliomyelitis acquired in utero or central neuritis, which he had studied clinically and pathologically, and after making five sections was in considerable doubt.

Dr. C. C. Hersman, of Pittsburg, Pa., stated that he believed any maternal impression would have to occur very early in life of the fetus. He reported the case in which the esophagus was entirely severed, which the mother atributed to the fact that she had seen a hog's throat cut while pregnant. He reported several other cases of abnormal fetal developments.

Case of Spastic Diplegia Occurring During an Attack of Pertussis with Autopsy.—Dr. J. H. W. Rhein, of Philadelphia, reported the history of a patient twenty months old, born after a normal labor and delivered without instruments, and had had no previous history of nervous disease; there were no cardiac symptoms, the lungs were normal and the eye-ground negative. The child's power of walking disappeared, and later there developed spasticity of the arms and legs, nystagmus, petit mal attacks and finally general convulsions just before death. Macroscopically the autopsy was negative, but microscopical examination revealed distention of the perivascular spaces, the vessels were surrounded with round cells, multiple small hemorrhages were found in the cortex, pons and cerebellum, and in the cord there was degeneration of the crossed and direct pyramidal tracts.

Dr. T. H. Weisenburg referred to the case of a canary bird which had been in the house with children suffering from whooping-cough, developing a cough and finally dying from diarrhea, after glycerin had been placed in its drinking water. Examination of the brain of this bird showed the blood vessels to be very prominent.

Dr. Moore referred to the question which arises as to whether the nervous affection is due to toxins or mechanical irritation in case of severe nervous disease following any of the acute infectious diseases, and reported a case in which a child became totally blind following an attack of whooping-cough. Ophthalmoscopic examination was negative, and the child afterward made a complete recovery. He attributed the condition to minute hemorrhages in the brain.

Dr. J. H. W. Rhein, in closing, remarked that the literature did not contain any reference to whether the disease could be developed in the lower animals, which he thought would form a very interesting study.

Encouraging Case of Locomotor Ataxia.—Dr. Guy Hinsdale, Hot Springs, Va., reported the history of a patient who is engaged in a large canning factory and has twice been under his care, being able to resume his occupation about three months after the beginning of treatment in the first attack. He has been married eighteen years, has no children, uses alcohol and tobacco, but denies syphilis. The second attack developed about three years later, with severe gastric crises and abdominal pains. Under treatment by rest, hypodermic injections of mercuric chloride, strychnine and gradual feeding, in connection with massage, electricity and educational massage, he gained 46 pounds in nine weeks and showed great general improvement.

Treatment of Acute Anterior Poliomyelitis by Nerve Anastomosis.—This paper was by Drs. W. G. Spiller and Charles Frazier, of Philadelphia. It was read by Dr. Spiller, in which he stated that in poliomyelitis the motor nerve cells of the anterior horns in a limited area are destroyed, and the nerve fibers having their origin in these cells degenerate, and following the destruction of the nerve fibers, the muscles formerly innervated by these nerve fibers atrophy. He believed, if the persisting paralysis is slight, there is hope of recovery of function by anastomosis of the peripheral end of a diseased nerve with a normal nerve, but the success of the operation will depend on the degree and extent of the persisting paralysis, the time at which the operation is done and surgical technic.

Dr. Wharton Sinkler, of Philadelphia, believed this to be one of the most important advances in the treatment of poliomyelitis, and felt that the time would come when it would frequently be done. He also referred to the fact that a similar operation had been done in the treatment of facial paralysis.

Dr. Albert E. Sterne, of Indianapolis, Ind., felt that the method had many advantages over tendon transplantation, as in this way one establishes normal function in a set of muscles already in existence, whereas in tendon transplantation you disable to a certain extent a group of muscles. He also urged the early institution of treatment by means of electricity, massage, etc., in cases of poliomyelitis.

Dr. David I. Wolfstein believed that early interference in cases of anterior poliomyelitis was illogical, until it could be determined to what extent the cord was diseased and to what extent the muscles were going to atrophy. He also believed tendon transplantation to be superior to the method of nerve anastomosis outlined by the author.

Dr. Howell T. Pershing, of Denver, Col., felt that while we should be on the lookout for every improvement in the treatment of this disease, the results of such an operation would have to be proven by more than one or two cases before we could come to such a decision. He believed that the use of electricity and massage or any other mode of nerve irritation was contraindicated in the early stages of the disease.

This paper was also discussed by Dr. T. H. Weisenburg, of Philadelphia, and Dr. C. C. Hersman, of Pittsburg, Pa., and Dr. Spiller, in closing, stated that he believed that in many of the cases the paralysis is limited to a small number of the muscles, and felt that the operation should be performed only in selected cases. He stated that the longer the operation was delayed the less likely it is to be successful and for that reason he had named the period of six months.

Some Unusual Forms of Multiple Neuritis.—This was read by Dr. Wharton Sinkler, of Philadelphia, in which he stated that the condition has only comparatively recently been recognized, the most common type being due to alcoholism. He stated that there are many forms of peripheral paralysis, which are due to multiple neuritis, and not recognized as such, among which are arsenic, used medicinally, lead medicinally, or as a cosmetic or absorbed in the occupation, septic multiple neuritis occurring after miscarriage, abortion or labor, and reported several cases illustrating each of these conditions.

Dr. J. H. W. Rhein, of Philadelphia, reported a case of neuritis occurring two weeks after childbirth in which the patient had had very little fever and no evidence of puerperal spasm.

Dr. Angell, of Rochester, N. Y., reported a case of neuritis from lead poisoning from chewing the lead seals from cars by an employee of a tobacco factory, who had done this for a period of two or three years, chewing two or three each day. He also referred to the case of a farmer in whom the disease had resulted from kneeling on the ground husking corn.

Dr. T. H. Weisenburg, of Philadelphia, referred to the cases of beriberi, which he had an opportunity of studying while an army surgeon in the Philippines. He stated that the disease seems to come from the place where the prisoners were confined, and that when they were removed to the other side of the prison there would be no more cases develop. He mentioned two forms, a dropsical form and a dry form, the latter giving the most grave prognosis.

THIRD DAY—JUNE 9TH.

Dynamometer for Measuring Perspiration.—Dr. H. E. Wetherill, of Philadelphia, said that the value of some method for the measuring the perspiration in such diseases as exophthalmos, diabetes insipidus, uremia, fevers, etc., was evident. He then exhibited a completed instrument and several charts showing the results by the different methods.

Minor or Borderline Psychoses.—This paper was read by Dr. Frank P. Norbury, of Jacksonville, Ill. The author reported several cases, considering in detail the various symptoms, and outlined the treatment for the condition, prominent factors in which were rest, isolation, careful symptomatic treatment during the period of evolution of the nervous, and watchfulness of the physician during convalescence. He believed the disease might occur either in continuous drinkers or periodic delinquents, and was rare in acute alcoholism, occurring most frequently after adolescence up to forty or fifty years of age. Early treatment is successful in most cases, although the prognosis depends to large degree upon the inherited frailties and moral developments.

Psychic Force.—Dr. Brooks Beebe, of Cincinnati, Ohio, gave full consideration to the nature, force and mode of expenditure of this element, commenting particularly upon the influence of one mind upon another; after which he dwelt upon the value of suggestive therapeutics and urged the necessity for greater knowledge of and more frequent use of this agent by the physician.

This paper was discussed by Drs. Arthur Conklin Brush, of Brooklyn; Howell T. Pershing, of Denver, Col.; W. J. Herdman, of Ann Arbor, Mich.; James H. McBride, of Pasadena, Cal.; Albert E. Sterne, of Indianapolis, Ind.; F. W. Langdon, of Cincinnati, Ohio; Richard Dewey, of Wauwatosa, Wis.; E. B. Angell, of Rochester, N. Y.; A. A. Searcy, Alabama; David I. Wolfstein, of Cincinnati, Ohio; Theodore Diller, of Pittsburg, Pa., and closed by Dr. Beebe.

Have Drug Habits a Pathologic Basis?—Dr. Albert E. Sterne, of Indianapolis, Ind., said that the hereditary and acquired influences in the development of the habit should be carefully considered, and attention directed to the fact that the physician, on account of his knowledge of the drugs, was frequently the easiest victim. He then considered the pathology under the heads of (1) Hereditary or psychocellular; (2) Acquired or pseudopathological; (3) Effect upon the system or true pathology. The pathological changes in alcoholism and the drug habits were compared and the fact noted that the habitual alcoholic shows more effect than the periodic user.

Dr. Pressey, of Toledo, Ohio, did not look upon heredity *per se* as an important factor in the development of alcoholism and the drug habits, but considered that they were more due to the situation, vitality and nerve force of the patient.

Dr. Sterne, in closing, considered the possibility of the chemical union of the nerve cells with the alcohol and dwelt at some length on the pathology of the condition.

Upon motion of Dr. Smith Ely Jelliffe, of New York, the Chair was instructed to appoint a committee to investigate the pathology of the opium habit. This committee was announced later to consist of the following: Drs. Smith Ely Jelliffe, Brooks Beebe and Albert E. Sterne, and one other.

Case of Locomotor Ataxia with Tremor Resembling Paralysis Agitans.—Dr. John H. W. Rhein, of Philadelphia, reported at length the clinical and pathological findings in a case of the disease, occurring in a man aged fifty-eight years. He stated that in addition to the usual symptoms of locomotor ataxia, there was present a tremor resembling paralysis agitans, but none of the other charateristic symptoms of Parkinson's disease. The characteristic lesions of locomotor ataxia, together with the signs of a general arteriosclerosis were revealed at the autopsy, but the lateral columns were unaffected.

Should Inebriates Be Punished by Death for Crime?—Dr. T. D. Crothers, of Hartford, Conn., said that inebriety in all its conditions is palsy and means serious impairment of the brain and its functional activities. He stated that the relation of free will and conduct are always obscured and free will and reason are abnormal; the brain anesthetized both locally and generally and profound psychosis exists. He believed punishment of inebriates for crime should be abolished and cited statistics tending to show that such punishment increased the crimes committed.

Dr. Brooks Beebe, Cincinnati, Ohio, did not recommend the abolition of the punishment of inebriates for crime, and felt that while the medical profession were agreed as to some grade of irresponsibility, yet the public needed protection.

Dr. S. M. Crowell, Charlotte, N. C., commented on the value of institutional treatment of inebriates, and referred to the fact that a bill was in course of preparation looking forward to the establishment of such an institution in Charlotte.

Autopsy Findings in Epilepsy.—Dr. B. Onuf, of Sonyea, N. Y., based his paper on autopsies performed at the Craig Colony. He exhibited a chart showing in detail the results of fifteen autopsies, giving in each case the age at onset and duration of the epilepsy, approximate number of attacks during life, distinguishing *petit mal* and *grave mal;* heart lesions (there being but one case that did not show some valvular affection) gross lesions in both hemispheres, thalmos, axis and cerebellum. He exhibited several photographs taken of the brains, both before and after the removal of the meninges, and stated that the cause of death in nine out of fifteen of the cases had been pneumonia. He also remarked that he had secured good results in the preservation of the bodies by means of an injection of 12 per cent. solution of formalin, and in conclusion urged careful auditory, ocular and physical examination and record.

Dr. W. G. Spiller, of Philadelphia, commented on the value of the clinical and aural symptoms and did not believe in stripping the meninges before studying the brain, feeling that careful study should also be made of it.

Dr. Onuf, in closing, remarked that while the pia was removed before the photographing of the brain, it had been preserved and studied.

Large Tumor of the Frontal Lobe.—The subject of Drs. Philip K. Brown, of San Francisco, and W. W. Keen, of Philadelphia. Dr. Keen read the paper, in which the clinical and pathological history and the operation were carefully outlined. The patient began in March, 1903, with bilious attacks followed by paralysis of the external rectus muscles, but no change in sensation. Complete hilateral anosmia developed about June and by the middle of July there had occurred a progressive loss of vision and mental dulness, progressive ophthalmoplegia and beginning left ophthalmos. The administration of Hg and KI produced no effect, and complete blindness followed the development of tenderness and pain on the left forehead and temple. A cerebral tumor of the left frontal lobe was diagnosed, and on August 5, an operation by means of a large osteoplastic flap of the frontal region was performed, which revealed the fact that the tumor, which was of the sarcomatous variety, had perforated the skull at several points and broken into the frontal sinus and ethmoidal cells. Owing to the size of the tumor removal was impossible, but in order to diminish pressure a portion was taken out. Recovery from the operation occurred, but local infection through the nose followed seven weeks later by coma and death took place.

Brain Tumor with Progressive Blindness.—Drs. W. C. Kendig and David I. Wolfstein, of Cincinnati, Ohio, reported this case. The patient was a traveling salesman, fifty-eight years old, with a history of syphilis and alcoholism in whom a diagnosis of possible paresis had been made, but which the autopsy revealed to be due to brain tumor.

Dr. Theodore Diller, of Pittsburg, Pa., reported several cases of brain tumor, in one of which the brain was eroded and there were protrusions and in another in which the bone was thickened and there were also protrusions. He also remarked the fact that Sir Victor Horsley performed operation of this character without the use of sutures in the dura mater.

Dr. Charles K. Mills, Philadelphia, Pa., commented on the differential diagnosis of brain tumors, and recommended early surgical interference, believing that an exploratory operation was justifiable in doubtful cases. He then referred to the fact that brain tumors of varying density and size might occur without producing headache, or any of the classical symptoms, or only one thereof, such as optic neuritis or optic atrophy.

Dr. Albert E. Sterne, of Indianapolis, Ind., reported the case of a station master who suddenly complained of pain in the left frontal region, accompanied by a delusion that he had made mistakes in his work and was to be arrested, etc. After going south for a vacation he became worse, was admitted to the sanitarium, and operation planned for the next day, prior to which time he had two convulsions and died, the autopsy showing infiltrating tumor of the brain.

Dr. F. W. Langdon, of Cincinnati, Ohio, reported in detail the clinical history of the case referred to in Dr. Wolfstein's paper, including the ocular and clinical symptoms for a number of years previous to his death.

Dr. F. X. Dercum, of Philadelphia, referred to two cases of cerebral tumor, in the first of which no pain was observed and in the other there was slight pain over the occiput, in each of which the tumor proved to be a sarcoma, and in the latter it was gangrenous.

Dr. W. G. Spiller, of Philadelphia, referred to the frequent difficulty of early diagnosis and reported several cases, among them being one of tumor over the pons extending down into the spinal cord, and the other in which there was thickening of the bone over the tumor due to infiltration of tumor.

Dr. B. Onuf, of Sonyea, N. Y., referred to cases of optic neuritis, in which accurate localization of the tumor could not be made, and raised the question as to whether it was advisable to operate at once in these cases, or wait until the tumor could be localized.

Dr. W. W. Keen, in closing, stated he believed it was advisable to insert sutures in the dura, even although the operation was slightly prolonged thereby, in order to prevent adhesions. He urged the necessity for early operation, not only in cases where the tumor has been accurately localized, but also in optic neuritis, such as the cases cited by Dr. Sonyea, and referred to cases in which the headache had been relieved by opening of the skull, although no tumor was removed.

Hysterical Delirium; Report of Four Cases.—Dr. Theodore Diller, of Pittsburg, stated that "insanity" as an expression of hysteria is apt to pass unrecognized as such when the patient is seen by two sets of observers—those inside and those outside of the asylum, as neither set of observers knows the case in its entirety. He referred to the fact that the delirium described by the Charcot school as the last phase of a "grand" attack of hysteria might occur as a more or less isolated symptom, and be so prolonged as to constitute a type of insanity, but that it exhibited certain marks which may lead to its recognition as an expression of hysteria. This he followed with the reports of four illustrative cases, all occurring in women of various ages.

Dr. Howell T. Pershing, of Denver, Col., reported the case of a young school girl, who first became unduly anxious about her school work, which was followed by talking much about animals and other nonsensical remarks, succeeding which she developed a state of delirium and continued therein for ten or twelve weeks, afterward making a good recovery, but having very little recollection of what had occurred.

Dr. F. X. Dercum, of Philadelphia, remarked upon the fact that cases of hysterical delirium were usually of short duration and felt that the temperature rise in one of the author's cases would rather point to an infection.

The discussion was closed by Dr. Diller.

Relation of States of Apprehension to Cardiac Disturbance.—This paper was read by Dr. William Rush Dunton, Jr., of Baltimore, Md., his observations being based on a study of twenty-five cases in the Shepherd Hospital and twenty in the Johns Hopkins. In the Shepherd hospital cases, five showed apprehension to a marked degree, three of which had cardiac lesions, and of the remaining cases five had marked cardiac lesions, but had never showed any signs of apprehension. Out of the Johns Hopkins Hospital cases eleven showed apprehension, in three of which there were various heart lesions and dyspnea.

Officers.—The officers of the Section for the ensuing year are as follows: Chairman, Dr. James H. McBride, of Pasadena, Cal.; Secretary, Dr. David I. Wolfstein, of Cincinnati, Ohio; Delegate to House of Delegates, Dr. F. W. Langdon, of Cincinnati, Ohio.

JOHNS HOPKINS HOSPITAL MEDICAL SOCIETY.

Regular Meeting held April 18, 1904.

Visceral Crises in Connection with Skin Lesions.—Dr. Osler discussed the surgical importance of this affection. He first gave an outline of the principal causes of colic, dividing them into five groups as follows: (1) The intoxications (lead, uremia and morphine); (2) functional and organic diseases of the nervous system (hysteria, tabes, etc.); (3) supradiaphragmatic diseases (pleurisy, pericarditis, angina, etc.); (4) disease of the abdominal organs; (5) disease of the pelvic organs.

The first case described was a girl, aged seventeen years, who had been admitted to the hospital for abdominal pain, which for six months previous to admission had recurred frequently in the left epigastrium and side. An abdominal section had been done, but the condition of the abdominal organs had been found absolutely negative. The patient's knee-joints were swollen and tender, but there was no skin eruption, and examination was negative. She left the hospital well. Two weeks later she returned with recurrence of the pains, with nose-bleed and with one purpuric spot on the left flank. In the Johns Hopkins Hospital a case of hematuria with recurrent "kidney colic" accompanied by erythema and angioneurotic edema has occurred in the past years, and two other cases of abdominal colic with skin lesions. Several similar cases have been recently reported in the *Journal of Cutaneous Diseases*. The first was a boy, aged five years, complaining of abdominal pain, who was operated on for symptoms of intestinal obstruction. No obstruction was found, but in two places the intestine showed hemorrhagic infiltration, and the next day a marked purpuric rash appeared. The second case, a boy of seven years, with purpura and bloody stools, died. At autopsy, besides an intussusception, hemorrhages were found into the peritoneum. In the third case of severe recurring abdominal pain, congestion of the bowel near the ileocecal valve was found at operation and two days later a crop of purpura appeared. The boy recovered, but the trouble recurred, bloody stools appeared and another purpuric rash. The cases may be divided into six groups: (1) Colic with angioneurotic edema (Quincke's disease). This often shows a tendency to occur in families, as illustrated by the Rush family, of Bordentown, N. J., in which several generations were affected; (2) colic with urticaria; (3) colic with purpura. This symptom complex, in which abdominal pain, purpura and arthritis occur, is known as Henoch's purpura. (4) Colic with fugitive erythema. (5) Colic with combinations of skin lesions in the various attacks. (6) Long continued recurrent colic, with skin lesions appearing very late in the disease. Of 29 cases, reported by Osler, seven died, all of a complicating nephritis.

Henoch's Purpura.—Dr. Cushing referred to a patient who had been admitted to the surgical side of the hospital with pain, tenderness and a leucocytosis. She was prepared for operation, with the idea that there was some acute abdominal trouble, but a bilateral purpura was discovered accidentally, a diagnosis of Henoch's purpura made, no operation done and patient recovered. Dr. Atkinson referred to a case of his own, in which there was recurrent abdominal pain closely resembling attacks of gall-stone or kidney colic. The appearance of a marked erythema, however, made it clear that the case was one of a visceral crisis accompanying a skin lesion. He said that he had also seen the condition after the administration of the antitoxin of diphtheria. In this patient a violent erythematous urticaria appeared over the whole body eight days after treatment. With it there was edema in both eyelids and a slight arthritis. The symptoms promptly disappeared.

Dr. McCrae referred to the association in these cases of constipation with the abdominal pain. This was especially noticeable in the first case reported by Dr. Osler, and as a rule in these patients the pain disappears when the bowels move. It may well be, if the pathology of the condition is some sort of a hemorrhage into the bowel wall that the transudation accompanying catharsis gets rid of this exudate and in that way relieves the pain.

Immunization of the Dysentery Bacillus by Its Growth in Agglutinating Serum.—Dr. Marshall and Dr. Knox reported work which they have recently done in this line. The work was done to see if experimental corroboration could be given to the suggestion made by Dr. Welch in his Huxley lecture, that one form of immunity was due to a change not in the cells of the body, but in the invading bacteria themselves. The work was done by injecting pure cultures of the dysentery bacillus into bouillon tubes containing a small amount of serum which would agglutinate these bacilli. It was found by subsequent study of the organisms so treated that the bacteria had been changed so that they could not subsequently be agglutinated by the same serum; in other words, that their receptors had been either lost or so changed that they were no longer susceptible for this agglutinin. Study of the serum itself after centrifugalization showed that the change had not occurred there for it still continued to clot inoculations of organisms from fresh cultures. The same experiment was subjected to several modifications in order to test it in every possible way and control tests were made in every case. The organisms were also studied after transfer through a series of about eighteen tubes. The work showed that there is a type of immunity due to a loss of susceptible receptors. The most frequent type, however, is, of course, that in which immunity is due to an overproduction of antibodies. These experiments may explain the existence of so-called paratyphoid and paracolon bacilli, which would then be understood to be merely immunized forms of the organisms themselves.

Stated Meeting held Monday, May 2, 1904.

Hydrocephalus.—Dr. Cushing showed a negro baby of eight months with this disease. The patient, the second child of healthy parents, had shown signs of this condition for three months and at present the parietal bones were 10 cm. apart. All the separate cranial bones could easily be outlined by palpation. The contained fluid was apparently under

great tension and the child's head had been tapped—200 c.c. of clear fluid having been drawn away from the ventricles. Circulation of the cerebrospinal fluid probably takes place from the choroid plexus to the longitudinal sinus and thence out through the sinuses to the circulating blood and the heart. The escape has usually been thought to take place via the Pacchionian bodies, but as these are not present in young infants or in anthropoid apes, and as complete injections are possible in both, this idea is probably wrong. Internal hydrocephalus is certainly due to some obstruction but Dr. Cushing doubted that this obstruction is situated at the foramen of Magendie, as is usually supposed. The operation now done is a lumbar one. A preliminary lumbar puncture is first done to make sure of a connection between the ventricles and spinal canal. The fluid is usually found to be under great tension. A trephine hole is then made in one of the lumbar vertebræ by means of an abdominal section, a silver drainage tube inserted and the spinal canal thus permanently connected with the postperitoneal loose connective tissue. Dr. Cushing has operated on four cases in this way. The first died of intestinal obstruction, the second and third immediately after the operation, but the fourth is now living (six months after operation), and the head remains nearly normal in size.

Chronic Alcoholism in Bellevue Hospital.—Dr. Lambert reported a review of his experience in this institution. In the past nine years 51,000 alcoholics have been treated there and of this tremendous number 66 per cent. were between thirty and forty-nine years of age. Delirium tremens is usually thought of as primarily a nervous condition; but the effect of alcohol on the heart and circulation is its most important effect. So far as the life of the individual is concerned, alcohol gives an early vascular dilation. It causes a fall in temperature (the lowest temperature recorded in this series was 80° F. by rectum). There is a direct or indirect stimulation of respiration and an inhibition of proteolysis when liquors are drunk rich in alcohol or in extractive content. A moderate amount probably increases digestive powers. As a food it takes the place of an equal amount of isodynamic carbohydrate and so protects the proteids; but in large doses it increases the proteid catabolism. A series of 125 cases was studied carefuly by Dr. Lambert. He found that, as a rule, male alcoholics live longer than female. The autopsies showed frequent heart lesions. Brown atrophy and fatty degeneraion often occurred. In the lungs edema and congestion were most frequently seen. In the liver fatty degeneration was found in about 75 per cent. of the cases. Cirrhosis was frequent, though it is interesting that this condition has never been experimentally produced in animals. The liver was normal in no case. Chronic fibrosis was the commonest condition seen in the pancreas. The kidneys were never normal, the nephritis being chronic in all but two patients and the parenchymatous variety being most frequent. In the stomach atrophic gastritis was found in 50 per cent. of the cases. Atrophy of the ovaries was frequently seen. The brain was almost always edematous; acute and chronic meningitis occurred frequently, and atheroma of the cerebral vessels was not unusual. The essential pathological processes caused by alcohol in the various organs of the body are hyperemia, degenerations (particularly of the fatty kind), and connective tissue proliferation. The cases are often treated entirely for their nervous symptoms when the circulation needs treatment most. The symptoms vary markedly with idiosyncracy and with the dilution of the alcohol used. The habit of chronic alcoholism is often started quite young—in many patients of this series before twenty-one years. The drug is taken not for its taste but for the narcotic effect—that is either to produce certain feelings of artificial well-being or to drown sorrows, pain, etc. It is not the fusel-oil but the larger amount of alcohol for the same money which makes cheap whisky so dangerous. By the coating of the tongue and the character of the tremor the length of a spree may be quite accurately estimated. Hallucinations of sight are most frequent and of smell quite rare, the most characteristic feature being the belligerent attitude which the patients assume toward their delusions. An acute infection or a blow on the head may bring on delirium tremens in a moderate drinker. Beer causes the condition slowly but it leaves as slowly. Patients who drink absinthe are particularly liable to convulsions. In this series the mortality was 3 per cent., but in the cases in which ergot was used it was only 1½ per cent.

Dr. Welch referred to the complete report of the Committee of Fifty on the physiological effects of alcohol. It was found that in rabbits receiving daily intoxicating doses of alcohol, though some died of alcoholism, many lived healthy for periods as great as three years. The changes in the ganglion cells were among the most frequent pathological conditions found in the central nervous system.

Cystinuria.—Dr. Campbell reported on a study of this condition, in which it was found that cystin probably represents a middle product in the metabolism of sulphur.

Distomiasis.—Dr. Emerson referred briefly to a case of pulmonary distomiasis, reporting the case for Dr. Stiles.

BOOK REVIEW.

Commoner Diseases of the Eye; How to Detect and How to Treat Them. By Casey A. Wood, C.M., M.D., D.C.L., Professor of Clinical Ophthalmology in the University of Illinois, etc., and Thomas A. Woodruff, M.D., C.M., L.R.C.P., Professor of Ophthalmology in the Chicago Post-Graduate Medical School, Chicago, etc. G. P. Engelhard & Co., Chicago.

This little book is admirable in its purpose and execution. The authors state that it is intended to consider ophthalmology from the standpoint of the physician in general practice. It is proposed, they state, mainly by describing only the commoner diseases of the eye, never using a technical term when a simpler word is available, by numerous illustrations, synopsis headings, and a complete reference index, to popularize a study that is often considered difficult and unprofitable. The illustrations are excellent with a few exceptions, in which too much seems to have been attempted.

In a book with such a modest purpose, it would seem that less stress might have been laid on operative measures, and perhaps more attention given to the observation of variations from the normal. The description of ophthalmia neonatorum with its treatment, of trachoma, and of diseases of the cornea, should be especially valuable to the general practitioner.

The chapter on glaucoma is good, and the operative treatment is given sufficient space to enable the general practitioner to estimate the gravity of the condition. The method given on p. 262 styled "An easy method of diagnosing the commoner forms of inflammation of the eye" is excellent as far as it goes, and should be committed to memory by all physicians, but it is a matter of grave doubt whether in its application it would be always easy.

ORIGINAL ARTICLES.

THE THEORY OF MUTATION IN ITS RELATION TO MEDICINE.[1]

BY JONATHAN WRIGHT, M.D.,
OF NEW YORK.

IN the discussion of the etiology of microbic disease, there enters, remotely it is true, but nevertheless irresistibly, a consideration of that long-laid specter which still starts up in every century of the history of science,—spontaneous generation. Scoff at it, deny it as you may, it is inevitably the direction toward which evolutionary science is drifting. It is foreshadowed in the monism of Häckel, it is touched but not demolished by the innovations of Mivart and of De Vries. Two years ago I had occasion to say:[2] "Certainly if evolutionary doctrine, if the fact of the mutability of the forms of life, means anything, it means that there has not only been a time, but there is every instant a time when matter is becoming endowed with vital energy which has the power to propagate its kind." This was but an unconscious echo of the tendencies of modern biology.

To gravely assert that "the origin of the germs of disease was probably in the remote geological past" is on a level with the faltering plea of a former generation that God ceased His miracles when man began to inquire into them. This drift of modern thought in biology is voiced in the bold suggestion contained in the essay of Dr. Bastian,[3] "On the great importance, from the point of view of medical science, of the proof that bacteria and their allies are capable of arising *de novo*." It is an emphatic plea for the acceptation of the heresy of spontaneous generation. As I have intimated, I am very much disposed to be that kind of a heretic myself, but in the light of recent researches, especially those of De Vries, we are not yet driven to the extremity of Dr. Bastian's suggestion.

I believe the theory of mutation in biology, if it is settled in the affirmative, will have a very important bearing upon our knowledge of the etiology of disease, and this must form an excuse for its intrusion in a medical essay.

It is known to all familiar with Darwin's work that one of the greatest objections, with which the early evolutionists had to contend, was the extent of geological time necessary for the evolution of higher animal life on the theory of natural selection, or in the better chosen term of Spencer, the survival of the fittest. As is well known, Agassiz, to the last, utterly rejected the idea, pointing out the evidence of the sudden appearance on the earth of the lower vertebrates. Mivart so modified the conception as to provide for the sudden birth of species. Darwin himself, though unable to adduce evidence of it even from his stupendous command of facts, expressed the idea that there might be sudden great variations in animals and plants, which, seized upon by natural selection, might produce more profound modification of the structure of living beings than seemed possible in the small range of individual variations on which he pointed out that natural selection does act.

De Vries, a naturalist of Amsterdam, has declared that such shocks or jumps in the life history of species is a fact and that such changes and not the slow process of Darwin are really the origin of species. By experimentation with many varieties of plants, from which he selected the primrose for more extended study, he has observed changes, which he calls mutations, and these changes were so sudden and profound that he has come to believe that all species at some time in their life history exhibit an excessive instability from which new and distinct forms arise. "A mutation occurs when one species is formed from another." "A species changes only when it produces others. Or, rather, it does not change, but continues to exist next to the species newly formed."[1] At these times the species are said to be in a period of mutability. With the primrose, De Vries declares that the rate at which he observed new forms, which he dignified with the name of species, was at the ratio of 1.5 per cent., *i.e.*, out of 100 plants arising from seed from one to two new species would be found. "Many species multiply exceedingly rapidly when they are transported to a new region where the conditions are favorable." It seems that it is then that the period of excessive mutability is apt to appear. He admits that the vast majority of the new forms perish from lack of adaptation to their environment.

Now, parenthetically, I must disclaim any ability to act as a critic of this idea of De Vries. It may or may not be similar to that of Mivart. I cannot see how the view of Dastré[2] is justified. I cannot see how it in any way upsets the fundamental idea of Darwin. It seems, if the facts have been properly interpreted, rather to amplify and establish it. I see little difference in principle whether the fittest of these great variations or the fittest of the smaller individual variations survive. It is, of course, a great discovery if true, but it by no means abolishes the necessity for natural selection. Dastré's remark that natural selection causes the death but not the birth of species, is sacrificing accuracy to epigram. Hitherto, in the discussion of evolution, it has not been neces-

sary to point out that a "sport" or a "mutation" form which immediately perishes seems hardly to be the birth of a new species, any more than a still born or sterile child is the progenitor of a new race.

As I have intimated, I am incapable of judging as to whether these examples of De Vries are recessive and degenerate forms which would all perish from debility were they not artificially grown. If we are to allow degenerate changes to the extent he has observed, I see no reason for denying the possibility of the changes which would survive and propagate under natural conditions. It would seem likely that future observations will show that De Vries has observed extremes of variability, and that there are many intermediate grades from small individual variations up to the forms radically different, capable of propagating their kind and incapable of inbreeding with the parent stem.

I simply desire to point out here, as Dr. Bastian has done for spontaneous generation, how important "the theory of mutation" is to the conception of microbic disease. Let us reflect how it would apply to what we know of the history of contagious diseases, and how we might explain an apparent gap in medical history.

In the decades preceding the middle of the last century, it was the common belief that from time to time the character of certain diseases changed in their clinical manifestations. That, for instance, during a longer or shorter time pneumonia presented sthenic types, suitable for bleeding, followed by asthenic types when such procedures were disastrous. It is occasionally heard to-day from stubborn skeptics, that the type of diphtheria has undergone a change from the severer infections of the days before the introduction of antitoxin, to the milder forms which are exhibited by cases to-day when antitoxin is in universal use. Apropos of this point one need only peruse the descriptions of throat inflammations in the works of Hippocrates to perceive that diphtheria is not sufficient to account for the severity of the cases with which he had to do, while they were much more numerous than the corresponding type of Ludwig's angina, which is a curiosity in modern laryngology. It appears probable that the ancients had forms of throat disease to treat other than we observe to-day. In the history of smallpox and phthisis we are familiar with the rapidity with which a previously isolated race of savages is all but exterminated by the irruption of these diseases among them.

Men have grown more instead of less migratory since Attila poured his Huns into Italy, but to-day it is individuals, not nations, who migrate. The contrary was the rule in the dark ages. The period before the Renaissance was marked by the migrations and the first intercommunications of various branches of the Indo-Germanic races. This was preceded by a period of restlessness, and of migrating invasions into Europe by the yellow, Tartar-Mongolian hordes under Attila, and these only terminated at the death of Genghis Khan. It is in this period of upward of a thousand years after the fall of ancient Rome that we seek the origin of smallpox, scarlet fever, measles, whooping cough, influenza, possibly even syphilis. I am not prepared to say that none of these existed in the five hundred years which stretch from Hippocrates to Galen. It is quite likely, as I have elsewhere pointed out, that the birth of new knowledge, the Renaissance, permitted the differentiation of various diseases not possible even in the palmy days of ancient Greece, but there were men in the world then of as acute a mentality as have ever existed since and yet, empirical classification aside, we search the ancient pages in vain for any sure indication of many a scourge which has since ravaged civilization.[1]

Do the cataclysms of the history of mankind which followed the fall of Rome and ended with the Crusades stand in the same relation to the birth of microbic disease, as do the upheavings of geological strata to the birth of species in the fauna and flora of the world? Did smallpox or scarlet fever spring from some harmless protozoon of the pre-Renaissance? Is measles a side issue of scarlatina? Is the same true of smallpox and cowpox? Did whooping cough originate from influenza?

I do not know whether these questions have been asked before, or whether an answer to them has been attempted or not. If the postulates of De Vries are established, there would seem a hope of knowing something of the origin of disease without tracing it back to a remote geological past, unchanged and unchanging.

The problem is a mixed one, as are all questions dealing with etiology. Change of food, climate and habits must as surely modify human cells and their products, with which students of immunity are at present so absorbed, as do these soils alter the bacteria which feed on them. Thus we may suppose many diseases as the resultants of primordial changes in the cell and the microphyte entered in the dark ages upon a period of mutability similar to the primrose in Holland, after it was carried there from America in 1613.

It is true that this is vague and speculative, but if plants may originate from "others by sudden but small changes, often so small as to be hardly visible to the neophyte, surely diseases may do the same." In the pre-Renaissance they seem indeed to have originated with a shock or jump and since then they have been more or less constant except for the minor changes to which I have alluded as changes in type. Just as with plants they may have been formed from a mother disease which may still exist.

If we are not familiar with radical changes in bacteria, we are becoming familiar with their minor variations, not only of form, but of function in the production of poisons to the animal cell. The tubercle bacillus, we are learning, is a pleomorphic microphyte, with as marked variations of function as of form, but we know nothing yet of the birth of a new species from it, and yet,

[1] The Nose and Throat in Medical History.

though tuberculosis is one of the most ancient of diseases, in view of what has been said above, we may be permitted to imagine, that in prehistoric times some hay bacillus in a period of mutability acquired that minute but sudden change out of which has been evolved the tubercle bacillus deadly to many widely separated groups of animals.

There is a significant fact to bear in mind. The newer the disease, the more limited its range among animals. Phthisis and pneumonia are coeval with the dawning of the history of man; diphtheria can be traced back to the Babylonian Jews. Reports of the influenza are hardly recognizable in the medical literature of the Greeks and Romans but they were the first to emerge from the obscurities of the dark ages. These diseases, somewhat in the order I have mentioned, are widespread in the animal world, but syphilis, smallpox, whooping cough, scarlet fever, measles, of later historical mention are also markedly less widespread in the animal kingdom.

Any student of medical history, familiar with researches in the wider fields of biology, must be struck, in the narrower domains of bacterial research, with the phenomena exhibited by certain families of microorganisms, among which are found parasites poisonous to man. The tubercle bacillus, varying only slightly in form and growth from the hay bacillus, mounts in virulence to man through the turtle and fish bacilli to the microphyte of phthisis pulmonalis. Amidst the great number of reported actinomyces only a few apparently poison the human cell, yet their morphology is all but indistinguishable. I'm not enough of a bacteriologist to speak as to other groups, but I am confident that better equipped observers could point out analogies elsewhere. Considering the countless numbers and the immense rapidity of their multiplication, can we imagine any other division of life in which, so readily as in unicellular organisms, could arise "those changes so small as to be hardly recognizable"? We must seek the evidence of it in the diseases they cause.

It seems to me, therefore, however sympathetic we may be towards Dr. Bastian's belief in spontaneous generation, the phenomena, both biological and historical, of microbic disease do not necessitate its assumption, and we have little ground for it in facts hitherto presented. We should keep it sharply in our minds that, whatever may be the trend toward this view, the labors of Löwenhoeck, Spallanzani, Virchow, Tyndall and Pasteur in the last two hundred years and more, have definitely thrown the burden of proof on its future advocates.[1]

[1] In the mail with this proof came the July number of the *Popular Science Monthly*, which contains an extensive review of recent work relative to the theory of mutation, to which the reader is respectfully referred, as it comes too late for the incorporation in this thesis of any facts which may bear on its application on medicine. It is written by Professor Hubrecht, a Dutch zoologist.

Appointment of Dr. Meyer.—It is announced in the new catalogue of Cornell University that Dr. Adolf Meyer has been appointed Professor of Mental Diseases.

RACE SUICIDE FROM THE GYNECOLOGICAL STANDPOINT.[1] [2]

BY EGBERT H. GRANDIN, M.D.,
OF NEW YORK;
GYNECOLOGIST TO THE COLUMBUS HOSPITAL.

IN medicine, as in other walks of life, it is wise to pause at times and to strike a balance. In particular is this true of the department of medicine which my audience cultivates, for in none has there been more ceaseless activity, in none more varying phases of change,—often not of the progressive type.

From the dawn of history woman has been a problem, and her indecision of mind and of body has caused man anxiety untold—it may be because of his equal indecision in make-up. As we stand on our eminence of to-day, and look backward into the valley of gynecology, rich in names of great departed, teeming with much which seemed truth and yet with what to-day we look upon as error, we are far too prone to swell with pride in consideration of the greater light at the summit, yet as we look beyond, toward the future, rash would we indeed be should we venture to predict the brightness ahead. Reflect, however; consider deeply; sift the chaff from the wheat, and you will find that even to-day we are groping in the dark and facing problems of greater moment than the past ever offered, at times indeed, grappling with similar problems as yet unsolved, and as far as human ken—if unbiased—can predict, unsolvable.

Wander back and see the man of immortal memory bent on solving the problem of the cure of vesicovaginal fistula; trace the gradual evolution of pelvic surgery and its merging into the abdominal; think of the years of bodily and of mental toil involved in the elucidation of the cellulitic doctrine and its burial under the weight of the peritonitic doctrine; reflect on the problems offered at the time when the mechanics of the pelvis appealed more precisely, and of the pyramids of pessaries erected only to crumble; consider the age of the intrauterine applicator, of the tampon, of the pelvic 'tinkerings," of the electrical fads. The men who struggled mightily to solve the problems of those days were as honest in intent and as strenuous in endeavor as you and I are to-day, facing as we do the problems of the present and laying the foundations of manifold problems in the future. Notwithstanding the fact that we are better equipped than our gynecic forefathers were, for we possess accurate asepsis, absorbable ligatures, deep experience derived from ample invasion of the peritoneal cavity,—when we strike the balance the enigmas offered us, the dilemmas we are astride of call for the same struggles toward solution as those so well mastered by Sims, Peaslee, Emmet, Thomas, Tait, Spencer Wells, and your own Busey.

Medical gynecology has wellnigh been shelved. The aim, the ambition is surgical. Too often the

[1] Read, by invitation, before the Washington Obstetrical and Gynecological Society, March 4, 1904.

[2] Received for publication March 10, 1904.

uterus, the tubes and the ovaries are roughly handled when the liver, the kidneys, the intestinal tract, constitute the elemental problem. The medical press teems with socalled new suggestions, and old methods resurrected and dubbed novel. The wheel turns, and too frequently the index points to the past, the needle beyond the pelvis, and the new methods and devices become ghosts and nightmares of torment to us. A little more discretion, a little more thought, a little less eagerness in the solution of pelvic and abdominal problems, might spare us many a Waterloo.

In allied branches of medicine, we have seen the practical stamping out of yellow fever from localities wherein it had been endemic for ages; we have witnessed the discovery which nearly robs that scourge of the past—diphtheria, of its terrors; medical men are armed for the extermination of tuberculosis, to such a degree that Boards of Health in many localities demand its report under penalty; puerperal sepsis has wellnigh been eradicated wherever the puerperal woman is under conscientious and educated care; active minds are at work in the endeavor to isolate the germ or toxin of that scourge of the human race,—cancer; such is the record of the present. And yet, to-day, the gynecologist and his broader brother—the general practitioner, appear apathetic in reference to greater scourges, such as those to which I ask your attention tonight.

The problem of great moment which faces us at the present—and I have in mind now not alone gynecologists but also the general practitioner—a problem which is as knotty a one as any which offered to our forefathers, is that which has been not inaptly termed "race suicide."

To the layman "race suicide" means the unwillingness of man to procreate, or of woman to bear children, either because the exigencies of life are so strenuous that it is of vital moment that no more mouths should be opened for food than there exists the wherewithal to supply the food, or else because the demands of social life appeal more to man and to woman than the honor of being termed father and mother. Hence arise resort to the manifold measures for the prevention of conception, and the solicitations to which we are constantly subjected for the interruption of gestation in those who, having sown the seed, should of right carry it to full growth.

This phase of the question concerns us as citizens. The definition is entirely too restricted to satisfy us as physicians and gynecologists. The problem is very complex. The race is suffering from the effects of suicide far more because of inaptitude for conception than from disinclination to assume the obligations which maternity may entail. Disease of the reproductive organs—acquired innocently or deliberately implanted, this is the medical side of the problem—the side with which you as gynecologists are so familiar. Furthermore, immature, incomplete, uncalled-for surgery on the pelvic organs,—this offers another aspect of the problem. To reach a solution of this vital problem, I invite your attention to the chief cause of "race suicide"—the gonococcus, and I shall ask you to endeavor to devise with me the solution of the problem of its extermination, the outcome of which would be a victory greater than any yet won concerning racial integrity, the more so because thereby the gynecologist would be deprived of nearly sixty per cent. of his operative work. Surely a very unselfish aim, and yet in line with that which constitutes the brightest jewel in medicine's crown—preventive medicine.

In the first chapter of Genesis we are told the story of the marvelous creation and the story of the lamentable fall of man. Milton, in his exquisite verse, thus describes a mental trait of our distinguished ancestor, Adam:

> "This woman whom thou madest to be my help,
> And gavest me as thy perfect gift, so good,
> So fit, so acceptable, so divine,
> That from her hand I could suspect no ill,
> . . . . . .
> She gave me of the tree I did eat."

History repeats itself! Let women to-day consult us for the relief of sterility, and man says "it is the woman's fault." Before I have finished with him I shall state facts which should cause the cheeks of this miscalled "lord of creation" to blush, since it is on his shoulders that the blame for the vast proportion of sterile marriages lies, and this is tantamount to "race suicide."

The laity do not realize, and we, as physicians, do not lay sufficient stress in our teaching, on the preponderating influence played by man in the causation of sterility in woman. Ruling out the deformities or the malformations of the male genital organs which deprive him of the power of doing his share in the act of procreation, let us consider man as fully endowed with the *power*, and next consider the manner by which he deprives himself of the power. And further, let us never forget that the faculty of performing the sexual act by no means entails the ability to procreate. Thus then, in laying the onus for the greater proportion of "race suicide" we acquit a fair proportion of males who are impotent through no fault of their own. Possibly the mumps, possibly the acute exanthemata have reacted to such an extent on the seminal vesicles as to have deprived them of function. In about six per cent. of sterility in woman, the etiological factor is man possessed—perhaps—of the power of performing the sexual act and yet lacking the elements which are essential to fecundation. Examination of the semen will at once rule out this small class from the wearing of the onus of blame. Such men we can but pity. The disease which enters chiefly into my argument to-night, as the main factor in the production of "race suicide," is of a different type, since it is acquired deliberately on the part of man—too often, under our present system of education, because man has never been properly warned in regard to its un-

toward consequences on woman, should he enter the state of matrimony.

It is only on reflection and close consideration that the physician realizes the extent to which gonorrhea is responsible, not alone for "race suicide," but also for disease in woman and for blindness in the child. To speak alone of sterility —it has been estimated that nearly 60 per cent. of males have gonorrhea, either acute or latent, and you will recall in the latter respect how cogent to-day is the conclusion reached over a quarter of a century ago by Emil Noegerrath which, in his time, called largely for derision. Nearly 45 per cent. of sterile marriages are traceable directly to gonorrhea. To strike an eminently fair average, in case of sterility, man is at fault in about 20 per cent. This is a percentage based on direct sterility. When we consider the diseases of woman which are traceable to gonorrhea—such as those which involve the tubes, the ovaries, the uterus, and thus interfere either with insemination or with the progress of pregnancy, a fact which in the end amounts to sterility, the percentage of blame attachable to the male rises greatly. I venture to state that it is a fact familiar to all of those present, that were it not for the operative work derivable from abdominal sections performed for disease of the uterine adnexa due to gonorrhea, 60 per cent. of this work would be uncalled for. Thus, in salient figures, appears man's rôle in the production of "race suicide" from the standpoint of gonorrhea.

It will be of moment to interpose here a few words in reference to another coccus which man frequently injects into woman with the result of adding to his already heavy burden of blame for "race suicide"—I refer to the coccus of syphilis. This coccus, whether acquired innocently or not, renders woman incapable, to the fullest extent, of performing one of the purposes for which marriage was instituted—the propagation of the human species. The rôle of syphilis is not by any means as marked as is that of gonorrhea, since the germ of syphilis is not so apt to prevent conception. Woman conceives, but, as a rule, she miscarries, and this, to all intents, amounts to sterility. Therefore, it has become the rule among us, that when a woman is sterile, for the reason that she has never born a child to term, we investigate the man's record.

In short, sterility in woman dependent on disease of uterus, tubes or ovaries, may in about 50 per cent. of the instances be settled by saying: "Ask the man," and he is the so-called lord of creation, strutting about after a fashion which should make the peacock blush. Of all the animal creation he shows the least regard for his mate in that he inserts into her system germs which not alone render her incapable of performing that function so dear to every good woman's heart—the bearing of children, but also implants in her diseases which in the course of time send her to you and to me for operation. I have dealt with man harshly, and yet, poor devil, it is not always his fault. Owing to our utterly inadequate educational methods in matters sexual, owing to the bated breath under which the words gonorrhea (clap) and syphilis (pox) are spoken by fathers and by mothers and by educators and pastors and legislators and, far too often to their shame, by physicians, the youth of our land enter into the nuptial contract utterly ignorant of the consequences, to the women they have sworn to guard and to protect, of an uncured gonorrhea or syphilis. This is where our responsibility as physicians and as gynecologists rests to-day. This is the problem facing us—the education of the laity in regard to the significance of these scourges, these social evils, these causes of "race suicide." I have endeavored to show that man is responsible for sterility in woman in fully 50 per cent. of instances. Could a nobler work be performed by us than to start a crusade—and not, as in the past, a silent one, against these diseases which are responsible for "race suicide," in its true sense, through the inculcation of knowledge in the minds of parents and the laity, as a body, in reference to the necessity of instruction of the young man as to the risks he runs personally, should he acquire them, and as to the risk he subjects the woman he marries should he carry them to the nuptial couch? Should we, through our moral influence along these lines,—and the only possible lines, be enabled to exterminate the gonococcus, preventive medicine would make the greatest of all strides, and yet we, the operative gynecologists, would be deprived of nearly 60 per cent. of our work! Woman, however, would be the gainer, the human race be immeasurably increased, "race suicide," as an opprobrium, would cease to be spoken of, and the unselfishness of the true medical man would again stand strongly in the foreground.

From the present standpoint, man is not the "lord of creation," but the "exterminator of the species." Kill the gonococcus by teaching man the danger to woman and to the species should she acquire it, and then man returns to the condition he is pictured as having been in before Eve tempted him with the apple and he weakly said to his Maker: "It is the woman's fault." The average Eve is ready to procreate: the average Adam is unable—chiefly because of disease acquired in ignorance of its foul sequelæ.

Would we tolerate the entrance into our homes of a man the victim of smallpox? Should we tolerate his entrance with great pox? The day is not far distant, should we do our duty along educational lines, when fathers and mothers will require a clean bill of health from Adam before he is allowed to defile Eve. In any event, Eve is entitled to know the consequences of mating with a foul Adam. When this devoutly to be hoped for day arrives, there will be in the land fewer Rachels weeping for their children, and not to be comforted, because they are not.

As I have reiterated above, according to my light, the solution of our problem lies in education. Prostitution—the social evil, is responsible to the greatest extent for the dissemination of

gonorrhea and of syphilis. In the toleration of this evil by society too much stress has been laid upon woman's part in dissemination and too little on man's. As has been customary with the latter from the beginning of the world, he points the finger of scorn at woman, he abets woman in the making of the prostitute the social outcast, and yet, were it not for the solicitations of the man, for his untrammeled licentiousness there would be few prostitutes. It is time that there should cease to be recognized a different code of morals for man and for woman. That which is wrong in woman is equally wrong in man, and in face of the diseases under consideration the man is the chief offender and the finger of scorn should be first aimed at him. The starting point in the crusade should be the inculcation of this fact into the minds of the laity, and for this we need a new and a radical system of education.

Segregation of the female prostitute, licensing, these and other measures have been tried and without avail, because, much as we segregate her, the male prostitute is in nowise restrained and exercises his prerogative of making new female prostitutes. The sexual instinct is a God-given instinct, its purpose being the perpetuation of the species. Man, largely through ignorance of the calamities following the misuse of this instinct, has converted it into one of extermination of the species. Ignorance being at the bottom of his folly, it follows that man, at the age when this instinct is established, should be educated in reference to its purpose and also in regard to the consequences if the instinct be misused. In how many families, not excepting that of the physician, is the pubescent youth instructed by his father or by his teacher in regard to sexual matters, which not alone concern him deeply but chiefly the woman—pure in every sense until he defiles her? The crusade of extermination, therefore, of these "race suicide" diseases, should begin in the family, and where more fitting place than in the family of the physician, the man who above all should be an exemplar in the matter under consideration? I take it that the average young man approaching puberty is not foul at heart. He has the making of the libertine in him, however, if he be turned loose to graze without the halter. Bridle him well through education in matters sexual, and I believe that at least one-half of the present percentage of these foul diseases will disappear. There remains the born libertine! the man who will not be educated! the type of man who glories in his conquests and boasts of the number of times he has had the clap. This man will continue to make prostitutes, this man will continue to befoul woman, and for him repression is the remedy. The laity is being educated in reference to the methods for the prevention of the dissemination of tuberculosis, educate similarly the laity in respect to these social diseases. In time there will arise in the land a loud cry calling for the suppression of the professional libertine, if need be by laying the strong hand of the law upon him. If you cannot appeal to the reason of such an animal, you can always appeal to his fear. These views may appear Utopian and I grant that to attain them calls for the shaking off of many a shackle handed down from ages. More difficult victories have been won, however, firmer bonds have been broken, and all other means having been tested and having failed after a most lamentable fashion, legislation must finally be invoked to check "race suicide" as we, the gynecologists, view it. Yet another phase, and this is the education of the young girl. We teach our daughters at the marriageable age the risk they run should they mate with the drunkard; we endow them with all the knowledge and the graces which enable them to shine in whatever social sphere they may be called upon to enter, yet, we tell them nothing about their sexual life and do not warn them against marriage with the libertine. Why should we educate the boy and not the girl? It is on her shoulders that shall lie heaviest the burden of infection. It is she who will weep for the children she lacks because of the foulness of man. It is her inherent right, therefore, to be educated in matters sexual, that she may avoid the rocks which otherwise her health and her life will strand upon. Nowadays, when the old-fashioned family doctor, the friend and the counselor of the family from birth to old age, has been eliminated, the gynecologist, in matters sexual, must take his place, and here within your grasp lies another victory to be won, another jewel to be placed in gynecology's crown. Of necessity you are brought the closest to the woman, and it is your right and your duty by dropping an advisory seed here and another there to open her eyes to facts which otherwise she may not learn. The sexual hygiene of woman extends even to the nuptial couch and we may properly tell the girl through her mother, or directly, that the man she is about to mate with should be required to submit a clean bill of health, lest all the voyage of her life be bound in shallows and in miseries. But this infringes upon the so-called professional secret, and here is another shackle to be broken. Let the laity look upon these diseases in their true light—as scourges to the race, fouler far than smallpox, than yellow fever, than diphtheria, and the laity will promptly place them in the same rank and be ready to join us in stamping them from off the earth, and the code of secrecy shall no more apply to the one than to the other.

116 West Seventy-sixth Street.

STERILITY DUE TO ABNORMAL CONDITIONS OF THE UTERUS.[1] [2]

BY IHRAM N. VINEBERG, M.D.,
OF NEW YORK;
ADJUNCT GYNECOLOGIST TO MT. SINAI HOSPITAL

In this brief paper it is my purpose to discuss only the more common abnormal conditions of the uterus that may give rise to sterility. I

[1] Read at a meeting of the Obstetric Section of the New York Academy of Medicine, February, 1904, as part of a Symposium on Sterility.

[2] Received for publication March 28, 1904.

shall endeavor to treat the subject from a practical standpoint, basing my statements chiefly on personal experience. To treat the subject exhaustively would require much more time than is allotted to me, and would not serve the aims of this discussion.

Sterility due to the uterus must be classified as primary and secondary. Primary sterility is that form in which the patient has never conceived. Secondary sterility is that form in which the patient has borne one or more children, but the last pregnancy and consequent delivery or other processes, has induced such changes in the uterus that the woman is unable to conceive subsequently.

PRIMARY STERILITY.

The most frequent cause of this form of sterility is the various degrees of arrest of development of the uterus. We will not enter into the various malformations that may result from an arrest of development, as good descriptions of them may be found in the various text-books on gynecology and obstetrics. What chiefly concerns us here are those degrees of arrested development that result in a uterus that is slightly below the normal size, or in a uterus in which the uterine or cervical canals are at an abnormal angle. Before we can form a good conception of this we must keep in our mind's eye the size and form of the uterus at the different ages ranging from infancy to puberty and adolescence.

I may state right here that the gynecologist finds no more difficult problem to solve than the determination in a given case whether or not the sterility be due to a uterus that is not sufficiently developed. How often does one hear that such and such a prominent gynecologist has told a patient she could never conceive as her uterus was undeveloped, and the woman shortly thereafter became pregnant and went to full term! So fully am I impressed with the pitfalls in this connection that I am always very guarded in my statements when on examination I find a uterus that is below the normal standard in size and shape. Less than a year ago a gentleman and his wife were here from Paris on a visit, and consulted me in reference to sterility. They had been married two years. The notes of my local finding were as follows: A decidedly small uterus, with an acutely anteflexed cervix, the body lies rather far back toward the sacrum and is drawn to the left side.

Diagnosis.—Arrest of development with retrodisplacement. I advised dilatation and curettage as a means to relieve the rather severe dysmenorrhea, but did not hold out much hope that it would cure the sterility. Nor did I state that the condition I found would account for the sterility. It is probable I passed a sound into the uterus, though there is no note to that effect in the record. My advice was not taken, as their stay here was of too short a duration. On their homeward trip the expected menses did not appear, and to be brief, about two months ago the woman was delivered of a girl at full term.

In the foregoing case, the passage of the sound may have removed a plug of mucus in the cervix and thus favored the conception, or what may be just as probable, is that my examination was merely incidental, and had nothing whatever to do with the conception that took place so shortly afterward.

Further, it calls for a great deal of experience in bimanual examination to be able to say definitely that the uterus is not of the size corresponding to full development. The sound is not of great assistance in these cases. I seldom employ it. Notwithstanding all this, and recognizing that errors are frequently made, one can, in the vast majority of cases, distinguish a uterus that is so far below the normal as to be the cause of sterility.

In my experience the most frequent form of arrest of development giving rise to sterility is that which results in a very small uterus, one not much more than half the size of the normal organ, with the cervix acutely anteflexed upon the body. In these cases both the cervix and the body are proportionately small. Menstruation, as a rule, sets in late, in the seventeenth or eighteenth year, is rather scanty, may or may not be attended with pain, and is usually regular until marriage, after which it becomes irregular, appearing only every two, three, or six months, and after two or more years may cease entirely. This is a singular phenomenon and is just the opposite to that which we might expect from the stimulation attendant upon sexual cohabitation.

These cases are, as a rule, hopeless. I know of no form of treatment that will benefit them, but I do know of several cases in which great harm had been done by the so-called treatment for developing the uterus.

The next most frequent variety is that which is commonly known as the "infantile uterus," with a long cervix and a very small body rather acutely anteflexed upon the cervix. Anyone who has examined a great number of these cases can readily distinguish them on account of the great disproportion between the body and the cervix. In palpating them one is reminded of an individual who is all legs and who has scarcely any trunk.

Dilatation and the insertion of a stem pessary for a week or longer are sometimes attended with cure in these cases. The prognosis is generally good if the patient is still comparatively young, let us say under twenty-five years of age.

The third variety is that which is generally described as "congenital retroversion." Both the cervix and the body are comparatively long and slender and seem to be in the same axis. The body lies retroverted to the first or second degree and considerably to the left of the median line. In these cases the arrest of development seems also to involve the ligaments, especially the broad ligaments, as well as the uterus. It is this form which baffles most surgical procedures, for remedying the existing displacement, owing to the poorly developed and short, broad ligaments.

When a ventrosuspension or a ventrofixation is attempted the operator frequently finds he is unable to draw the body of the uterus up to the abdominal parietes. Even if he succeeds in suturing the body to the abdominal wall, in a very short time it will be found in its old faulty position, so great is the traction of the shortened broad ligament upon the uterus. Great judgment is required to differentiate these cases from those of retroversion brought about by inflammatory changes of the pelvic structures.

So far as treatment in these cases is concerned, my experience is that no surgical procedure of which I am aware will cure the sterility. I do not wish to express thereby that these women are doomed to sterility. Some of them become pregnant and go to full term. But when they do, it is not on account of any surgical method that may have been carried out, for the position of the cervix is such that there is no hindrance to the entrance of the spermatozoa to the uterine canal. When conception does not take place the fault lies elsewhere than in the position of the uterus. It is usually because the development is so far below the normal that the uterus is unable to perform the function of generation.

The other common forms of malformation on the basis of arrest of development that are usually attended with sterility are (1) a peculiar formation of the vaginal portion known as "conical cervix," and (2) the occurrence of a very minute os externum, known as the "pin-hole os."

The conical cervix is very characteristic in its shape and is easily recognized. It is best detected either by digital examination or by Sims' speculum, as the bivalospeculum puts the vaginal mucosa of the vaginal vault on the stretch and alters the shape of the cervix. The cervix has a decidedly tapering appearance and frequently the anterior lip is sharp and stands out very prominently. It is in this form that the transverse ridges on the anterior aspect of the cervix are frequently observed. They were first described by Saenger, and to my mind are due to redundancy of the vaginal mucosa owing to the diminished caliber of the cervix. If the remainder of the uterus is fully developed, as it may be, the results of stretching of the cervix with the maintenance of the dilatation for a week or longer by a stem pessary or gauze packing is usually attended with good results.

Pine-Hole Os.—The os externum, to justify such a designation, must be exceedingly small, not larger than the caliber of a small surgical probe. Some of these cases give the impression of being secondary to an endocervicitis in infancy or childhood. As a rule there is an accompanying endocervicitis, but this, however, may be the effect rather than the cause of the stenosis, and may be due to imperfect drainage. If the stenosis of the os externum is the only abnormality the prognosis is generally good. A mere stretching is seldom sufficient. Some plastic surgery must be done to make a new, good-sized os. Olshausen is of the opinion that stenosis of the os internum is more frequently the cause of sterility than that of the external os. In my opinion both varieties are not infrequently met with. This much is certain, that there is less risk of an error in diagnosis in stenosis of the external os than in stenosis of the internal os.

Some authorities deny that stenosis of either os can be the cause of sterility. They maintain that if the menstrual blood can escape from the uterus, the passage must be large enough for the entrance of the spermatozoa. There seems to be some force in this argument, for it is surprising through how minute an opening the spermatozoa may enter into the genital tract and impregnate the ovum. Some years ago I excised a hypertrophied hymen from a woman who was four months pregnant. No point of entrance in the hymen could be seen until it was held up to the light, when an opening not larger than a pin point was detected in its center. The excised hymen was double the thickness of the ordinary vaginal wall. Of course, in the case of the stenosed cervix there is always some mucous discharge. The force of the flow of blood from the uterus is sufficient to drive the mucous plug before it, while, on the other hand, the mucous plug may serve as a sufficient barrier to the migration of the spermatozoa upward.

Malpositions of the uterus in the nullipara may exist from other causes than arrested development. Retroversions of the uterus without the characteristics known as congenital I have seen in young women time and again. It is not my province in this paper to discuss their pathology. Whether they are always due to inflammatory processes of the adnexa and the pelvic peritoneum, is a matter of dispute. Let their pathology be what it may, this I know, that such a malposition may be the cause of sterility, and that impregnation frequently follows if the displacement be corrected, be it either by means of a suitable pessary or by some proper surgical procedure. Impregnation may occur in these cases even without correction of the malposition, but the pregnancy is usually interrupted between the second and fourth months.

Pathological anteflexion of the uterus not of developmental origin is not an uncommon condition, and is prone to be attended with sterility. There is scarcely any other disease of the uterus in which errors of diagnosis are so frequently committed as in this one. The reason is obvious. Normally the cervix is in a position of a certain degree of anteflexion, and even specialists with vast experience will differ in a given case as to whether the existing anteflexion is within normal bounds, or comes under the head of the pathological variety. If it were possible to define in a few sentences the points of differentiation between a normal and a pathological anteflexion, the preceding sentence would be not only superfluous, but not in accordance with the truth. It is useless, therefore, for me to endeavor to state the points of differentiation.

Schultze's dictum that the pathological ante-

flexion may be recognized by its immobility is more euphonious than practical. In my own practice I am guided in my diagnosis of a pathological anteflexion by finding the body of the uterus of usual size, the cervix comparatively large and forming a very acute angle with the body. In these cases I have obtained excellent results, with the operation devised by Dr. E. C. Dudley, of Chicago. This consists in splitting the posterior lip down to the internal os and suturing the flaps so that their ends meet at the highest point of the incision. I have had ten cases, at least, in which sterility of several years' duration has been cured by this method. The secret of success with it lies in the ability to select the suitable cases. In cases of acute anteflexion with marked arrest of development, as outlined in the beginning of this paper, the operation cannot fail to be unsuccessful and to bring discredit upon the operator.

Of the other uterine conditions that may be the cause of primary sterility, endometritis of gonorrheal origin deserves more than a passing notice. Before discussing this form of endometritis, let me say that endometritis in the unmarried and the newly married may occur from other causes than gonorrheal infection. We need only to bear in mind how common it is to have affections of the mucous membrane of the genital tract as a complication in the acute infectious diseases of childhood. An endometritis so pronounced as to be a barrier to conception is readily recognized. In addition to the profuse leucorrheal discharge there is generally a large area of erosion surrounding the external os. The chronic inflammatory process may produce such changes in the appearance of the os as to mislead the inexperienced into the diagnosis of a laceration. As a rule a thorough curettage, together with a cauterization of the erosions and the maintenance of drainage for a week or longer, will effect a cure. In some cases where the growth of the new tissue is very marked it may be necessary to make in addition a circular excision of the area of erosions and suture the new os to the vaginal mucosa as in an amputation of the cervix.

We now come to the consideration of endometritis of gonorrheal origin as a cause of sterility. This form of endometritis as an etiological factor in barrenness, to my mind, has been and is given undue weight, a legacy which we still inherit from Noeggerath's famous dictum. We have only to bear in mind the frequency of blenorrhea in the new-born to be made fully aware of this exaggeration. For the gonorrhea in the genital tract of the mother, which infects the eyes of her infant, has not been acquired during pregnancy, but, as a rule, before conception has taken place.

It can be readily understood that there would be a barrier to conception during the first few weeks of the infection when there is profuse purulent discharge almost filling the entire uterine canal. But when the process has become chronic, the secretion scanty and frequently mucoid, and when, as it has been demonstrated, the gonococci are limited to small areas, the cause of the existing sterility must be sought elsewhere, and will usually be found in the changes that have been wrought in the tubes.

After due consideration and an impartial weighing of the evidence as presented by a thorough bimanual examination, it is thought that the gonorrheal processes in the cervical and corporal mucosa is the cause of the sterility; the same treatment is applicable as for endometritis in general. I would make this difference, however, that following the curettage I would apply a 20 per cent. solution of nitrate of silver freely to the whole uterine canal and would pack with iodoform gauze. It may be neecssary to repeat the nitrate of silver application several times to effect a cure. It need scarcely be added that the treatment is justifiable only when the disease has become chronic. Acute gonorreal endometritis must not be tampered with.

Fibromyomata are the only growths of the uterus as a cause of sterility that need concern us to-night. The other growths are too rare as an etiological factor to merit our discussion.

Fibroid growths of the uterus are an uncertain factor in causation, for conception may sometimes occur in a uterus that is studded with them; on the other hand, a single small growth may be so situated as to prove an impassable obstruction to the spermatozoa. A small growth situated in the cervix near the internal os may have a double action: (1) in presenting an obstruction, (2) in bringing about a retroflexion of the uterus.

Olshausen collected the statistics of 1731 cases of fibromyoma, in which 520, or 30 per cent., of the women were sterile. This percentage is generally considered as rather high. In those cases described first by von Recklinghausen as adenomyomas, sterility is the rule, as these growths occur chiefly, and, according to von Recklinghausen, only in undeveloped uteri. Some authors claim that the subserous variety is attended with a higher percentage of sterility than the other varieties. Schorler collected 253 cases, and found nine per cent. of sterility in the myomatous polypi, 18.7 per cent. in the cervical growths, 24.7 per cent. in the interstitial growths, 38.8 per cent. in the submucous variety, and 47.8 per cent. in the interstitial variety. Gusserow, on the other hand, states that most of the recorded cases of pregnancy in fibroids have occurred when the growth was subserous.

Fibromyomata may also be the cause of secondary sterility. The growths in these instances either have not developed until after the first or second pregnancy, or were so small as not to interfere either with conception or gestation. I have not had the time to look over my own cases in reference to these points. In a general way I know that though I have seen a large number of cases of fibroids of the uterus, I have seen but very few in which pregnancy was present at the time of observation. A great number of the cases were observed in women who had never been

pregnant, while there was a good percentage who had given birth to one or more children.

SECONDARY STERILITY.

The most frequent conditions of the uterus giving rise to secondary sterility are (1) chronic metritis, and (2) very deep lacerations of the cervix.

Chronic metritis.—A puerperal uterus that fails to undergo proper involution will after a time have an increase of its connective tissue, so that the organ later becomes more fibrous than muscular. A certain degree of endometritis usually attends chronic metritis; but in some cases the endometrium may be fairly healthy, in which case pregnancy may occur, only to be interrupted at any time between the fourth and twelfth week of gestation. In some cases the diseased uterus may battle with its contents for even a longer period, and the miscarriage not occur until the sixth month or later. The condition is easily diagnosed by finding a uterus double or treble the normal size, very hard in consistency and more or less sensitive to pressure. The woman, as a rule, complains of various nervous symptoms, and a prominent symptom is the sensation as if something is moving about in the abdomen. If chronic metritis is seen at an early stage, some benefit may be derived from the various therapeutic measures recommended, but in the advanced stage I know of no procedure that will afford any relief.

Laceration of the cervix.—In order that a laceration can be the cause of sterility it must be very deep, and usually extends beyond the vaginal junction. Such lacerations are generally unilateral and give the impression as if the tear had extended beyond the os internum and into the body. No doubt, many of these cases are instances of slight degrees of rupture of the uterus that have undergone a natural cure. Lesser degrees of tears, when they are bilateral and attended with marked eversion and hypertrophy of the lips, may be attended with sterility. Still it is surprising how readily conception, which may even end in a full term gestation, may occur in very severe degrees of laceration with more or less thickening of the lips. In the form of laceration first spoken of the repair needs to be done by an experienced and skilled hand in order to meet with success. In the second form with marked hypertrophy of the lips, the operation that will give the best results is a partial amputation.

Other conditions of the uterus giving rise to secondary sterility that require a passing notice are permanent hyperinvolution and atresia of the uterus, following a rough curettage during the puerperal period, or a too vigorous curettage with or without the application of a caustic to the endometrium at a non-puerperal period.

Permanent hyperinvolution of the uterus.—As I have previously pointed out on two occasions, normal involution results in so-called hyperinvolution, that is, if involution has progressed to the full physiological extent, the puerperal uterus is reduced to a size appreciably smaller than the normal parous organ. It may only be half the size of the normal uterus. As this degree of involution is favored by lactation and is rarely seen except when the woman nurses her baby, it is commonly known as lactation atrophy. It is a temporary condition coexistent, as a rule, with the period of lactation. But occasionally, indeed very rarely in my experience, from causes into which we need not now enter, the uterus remains in this condition of undersize and is unable to fulfil its functions of menstruation and gestation. We then have a pathological or permanent hyperinvolution of the uterus. The only treatment that can offer any success in these cases is that which partakes of prophylaxis. If a woman continues nursing her infant until the eighteenth month or longer, and the menses have not recurred, and on examination the uterus is found below the normal size, the child should be taken from the breast at once and the mother placed upon a tonic and building-up treatment.

Atresia of the uterus following too vigorous curettage has already been mentioned and does not call for extensive description. It may be added that amenorrhea and consequent sterility may follow such a curettage even without the production of atresia. The endometrium simply fails to regenerate, because the curette has scraped away the tissues too deeply, not leaving enough of the glandular structure to build up a new endometrium. This danger alone, apart from many others of even a more serious nature, should make the general practitioner very wary of curetting the puerperal uterus.

I am conscious that I have treated the subject at hand in only a very fragmentary manner, but if I have been able to throw out a few practical hints in the recognition and treatment of sterility due to the uterus, I shall be content.

STERILITY FROM VAGINAL CAUSES.[1]

BY JAMES N. WEST, M.D.,

OF NEW YORK;

PROFESSOR OF DISEASES OF WOMEN IN THE NEW YORK POST-GRADUATE MEDICAL SCHOOL, AND ASSISTANT SURGEON TO THE WOMAN'S HOSPITAL IN THE STATE OF NEW YORK.

A division of sterility in women into causes due to derangements of any particular parts of the system of generation we must at once recognize as arbitrary and impossible to establish, since such derangements grade insensibly from one part to another, the whole condition being sufficient to establish sterility while that existing in any one part alone might not do so.

A study of the subject in this way, however, has its advantages in that it concentrates the attention more upon details which might otherwise be lightly considered. The part which the vagina takes in the physiology of reproduction is that of the chief organ of copulation in the female. Its function is to produce an ejaculation of semen from the male and retain it in a healthy condition

[1] Received for publication March 22, 1904.

in such proximity to the cervix that it may readily find access to its canal. Therefore, we may say in a broad and general way that in so far as the vagina fails in the above-mentioned functions it tends toward producing a condition of sterility. It is surprising to observe how obstacles in the vagina pathological, artificial and congenital are overcome in the efforts of nature to reproduce the species.

Skene quotes a case where the vagina was the seat of a cyst as large as the foetal head and yet conception took place and delivery could only be accomplished by its puncture.

Hirst mentions a case of congenital atresia admitting only a small surgical probe, yet pregnancy occurred.

In the celebrated case of Louis, quoted by P. Müller and others, pregnancy took place by the rectum, the upper part of the vagina opening into it. This was the occasion for a papal bull, for this purpose issued by Pope Benedict XIV. permitting intercourse in that way. The author has seen a case of complete procidentia with consequent inversion of the vagina where impregnation occurred. Cases have been familiarly quoted where conception has occurred, though the hymen was unruptured, and of such a character that it could not possibly have admitted the male organ. Yet, notwithstanding these facts, our premise that anything which interferes with a normal condition of the canal of copulation tends toward sterility is true, and these cases are exceptions.

We will now consider more in detail the departures from the normal and for the sake of systematic study divide the subject in the following way, leaving out artificial interference: (1) Congenital causes; (2) pathological causes; (3) traumatic causes; (4) psychical causes.

1. CONGENITAL CAUSES.

Pseudo-Hermaphroditism.—This condition as a cause of sterility is of considerable importance from its comparative frequency. The author has seen two cases within the past year in which the determination of sex was most difficult. These cases have not had the attention which they deserve from the point of view of sterility. In them sterility is almost invariably the rule, and not only is the imperfection of development in the vagina but in the other organs of generation as well. These patients are usually the victims of well-meant but ill-judged interference on the part of their medical advisers.

It seems to the author that the advice in such cases, the diagnosis having been thoroughly established, should be prompt and firm. They should be informed of their unfitness for the marital relation, of the outlook for sterility and advised to seek some useful occupation and give up all thoughts of matrimony. I consider it unwise and unfair to tamper with these ill-developed organs, endeavoring, for instance, to convert the uncertain sex into a female by amputating the rudimentary penis and establishing an artificial vagina. Grant that the operation has been so far successful as to make a somewhat close approach to the female organs, is it not bitterly unfair to the other party to be joined by holy wedlock to such a being?

Congenital Absence of the Vagina.—The author has seen one such case. The patient was of a well-marked feminine type. Careful examination showed no trace of a canal, but the presence of a mass the size of a fetal head occupying the situation of the uterus. A diagnosis of retained menstrual fluid was made. Dr. Bache Emmet operated upon her at the Post-Graduate Hospital to make a vagina and release the fluid. No trace of a canal was found throughout and the mass proved to be a sarcomatous uterus with no retained menstrual fluid present.

Vaginal, Septa and Bands, Double Vagina.—These cases are common and occur as a result of the failure of development of the ducts of Müller, the two canals failing to a greater or less extent to coalesce into one. They are often accompanied by imperfectly developed uterus and tubes. They may cause imperfect sexual connection.

Congenital Atresia.—Such cases are comparatively rare, and it is not uncommon to find in them that the urethra has become dilated and that the sexual act takes place through it, thus diverting the semen into the bladder.

Unusual Passages Due to Congenital Malformations.—Cases have been authentically reported where the upper part of the vagina has opened into the rectum or bladder, an opening in the normal situation being absent.

Persistent Cloaca.—Roberts calls attention to a class of cases where the normal anus is absent and by imperfect growth downward of the perineal partition the rectum opens into the urogenital sinus, not the vagina, for the ducts of Müller have not grown downward to form its lower part.

Imperforate Hymen.—Such cases are rare, and if other organs are normal the attention will be drawn to the abnormality early in puberty by the disturbance due to retained menses.

2. PATHOLOGICAL CAUSES.

These being the most frequent, are necessarily the most important causes of sterility due to the vagina.

New Growths.—The vagina may be the seat of any kind of new growth, but only five varieties may be mentioned as occurring sufficiently often to demand consideration as related to this subject.

Carcinoma of the Cervix.—Cohnstein has investigated this subject, and while his statistics show that this condition has a decided tendency toward sterility, in a fair proportion of cases it does not prove a bar to conception. This subject will be touched upon again when considering the effect of abnormal discharges.

Sarcoma.—This may find its origin in the cervix or uterus and obstruct the vagina or may originate from the vagina, usually the anterior wall.

Vaginal Cysts.—These usually occur in the anterior wall, and may reach considerable size. They have their origin in this situation as a rule from the ducts of Gärtner.

Fibroids from the uterus or cervix occupying the vagina.

Syphilitic Growths. — These sometimes resemble malignant tumors so closely that a diagnosis may be made only by microscopical examination of a section of the tumor.

Inflammatory Conditions Resulting in Abnormal Secretions Inimical to the Life of Spermatozoa.—This we must believe is frequently the cause of sterility. The following facts in regard to the agents which effect the vitality of spermatozoa are of great importance and have been established by many experimenters. The normal semen is faintly alkaline in reaction. Vaginal secretion faintly acid and secretion from the cervix faintly alkaline. A faintly acid secretion stimulates the movements of spermatozoa. A pronounced acid at first stimulates and then causes them to permanently cease their movements. A faintly alkaline secretion favors the continued life of the cells, and a powerfully alkaline medium kills them. Thus we see that any marked departure from the normal reaction of the secretion from the cervix or vagina must tend toward sterility through destruction of the spermatozoa. They are also quickly killed by contact with water. Hence a profuse discharge of unusual reaction from endocervicitis, an irritating discharge from carcinoma of the cervix or vagina, or a vaginitis with profuse and acid discharge, must all have an important action in destroying the life or activity of spermatozoa with consequent induction of sterility. The same condition is also brought about by the presence of urine in the vagina.

3. TRAUMATIC CAUSES.

Among these causes vesicovaginal fistula is one of the most striking. We would expect sterility here from the presence of urine in the vagina, but the cessation of menstruation and ovulation in many of these patients during the existence of the fistula is a curious phenomenon. Destruction of the perineum seems to have but little influence. Also the presence of cystocele or rectocele. Complete procidentia, however, is usually accompanied by sterility, but child-bearing has been often observed under these conditions. Hirst has reported a case of traumatism, from copulation, resulting in a false opening into the rectum through which this act was continued. Such cases, however, must be extremely rare, and are only mentioned as possibilities.

Atresia of the vagina due to disease or trauma also occurs, and may be a bar to normal insemination. Injury or former disease of the vagina may set up a condition causing vaginismus which seriously interferes with cohabitation.

4. PSYCHOLOGICAL CAUSES.

Incompatibility seems to have been fairly demonstrated in a limited number of cases by good observers. Cases are quoted where, the marriage relation having been continued for a considerable length of time without progeny, each party having contracted a new alliance, has proved fertile. Under this head also may be included many cases of vaginismus where the distaste for the sexual act sets up a reflex contraction of the sphincter muscles of the vagina (the sphincter vagina and levator ani) of such violence as to prove an effectual bar to copulation.

TREATMENT.

In cases of congenital malformation of the vagina where the other organs are demonstrated to possess their normal functions our personal consideration for the subject of the deformity is such that we are justified in resorting to any reasonable surgical measure for correcting it, and in this we must realize that we are largely controlled by sentiment. In the breeding of any other animal except a human being we would be controlled by judgment and the imperfect specimens would not be used for this important purpose.

The treatment of pathological conditions must naturally have been suggested by the enumeration of the causes themselves. In the case of new growths they should be removed, but when of malignant character, conception should be guarded against. Where the growth is of syphilitic origin the use of the mixed treatment with mercurials and iodides will usually prove effective. Where the sterility is due to an excessive and acrid secretion of acid mucous, it may be relieved by the judicious use of antiseptics and local applications, among which the very best is nitrate of silver. The applications should be made in strength to meet the conditions usually varying from 20 to 40 grs. to the ounce. Several such applications may be necessary at intervals of about one week, in the meantime a cleansing and astringent douche of creolin, one dram to two quarts of water, and one teaspoonful of fluid extract of white oak bark, may be administered two or three times daily with the patient in the dorsal position. Excellent results also may be obtained with other antiseptics as potassium permanganate, bichloride of mercury, lysol, etc. Local applications of alcohol sometimes seem to have a very beneficial effect.

There are several new proprietary preparations of silver in use, none of which I believe to be as effective as the nitrate of silver of the Pharmacopœia.

The relief of sterility due to traumatic causes offers a wide field of usefulness, and to attempt a specific description would lead us into a field too broad for the scope of this paper, but operations for the relief of procidentia, cystocele, rectocele, lacerations and vesicovaginal fistula at once suggest themselves. Where sterility is really due to psychological causes the physician can offer practically no relief, the means for this lying with the individuals affected.

Finally, each case should be carefully studied

on its own merits, and the etiology thoroughly established; we should map out a definite plan and persist in this until relief is afforded.

YOHIMBIN; ITS USE IN THE TREATMENT OF EYE, EAR, NOSE AND THROAT DISEASES.[1]

BY J. H. CLAIBORNE, M.D.,
OF NEW YORK;
ASSISTANT SURGEON, NEW AMSTERDAM EYE AND EAR HOSPITAL;
AND
EDWARD B. COBURN, M.D.,
OF NEW YORK;
ASSISTANT SURGEON AND PATHOLOGIST, NEW AMSTERDAM EYE AND EAR HOSPITAL, NEW YORK.

YOHIMBIN is a new alkaloid derived from the yohimbehe tree, a native of West Africa. This drug crystallizes in the form of white needles, having a silky appearance. It is readily soluble in ethyl, methyl and amyl alcohol and in ether and chloroform, but is only soluble in water to the amount of about two per cent.

The hydrochlorate is the salt usually employed and is fairly stable except in solution when it deteriorates rapidly. Solutions over a week old cannot be relied upon. It may, however, be preserved much longer by the addition of a small amount of chloroform.

Yohimbin has been much praised as an aphrodisiac, though but little has been written about it as a local anesthetic. Various observers have proved that it is non-toxic when injected in doses of 25 c.c. of a one per cent. solution of the hydrochlorate. After its injection a local anesthesia is produced which lasts for 1¾ hours.

Magnani (*Annali di Ottalmologia,* XXII, Nos. 5 and 6, 322, 1903) has reported that it causes anesthesia of the cornea and conjunctiva when dropped into the conjunctival sac. In a later article (*Clinica Moderna,* No. 35) he states that it causes considerable smarting when freshly prepared, but that this smarting subsides with the onset of the anesthesia. Tactile sensibility of the conjunctivia is obtunded in one minute after the application of the solution of the drug, and in five minutes the cornea begins to lose its sensibility, being completely anesthetized at the end of ten minutes. In about half an hour sensibility begins to return and is completely regained in about an hour. Sometimes the pupil is contracted and sometimes dilated and the movements of the iris are sluggish. The drug has no effect on accommodation.

Very shortly after the solution of yohimbin is instilled into the eye hyperemia is observed which persists for several hours. It is not so marked in old solutions. As might be expected, chloroform, when added to the solution for preservative purposes, increases the smarting but does not interfere with its action.

Because of the hyperemia which it causes, Magnani suggests its use in chronic affections of the eye which require stimulation. He compares and prefers it to tropacocaine because its effect is longer and because it is non-poisonous. Cocaine affects the epithelium and impairs the nutrition of the cornea, causes mydriasis and hypotony, and is toxic; for these reasons a satisfactory substitute is desirable.

The experiments and conclusions of Dr. Claiborne to determine the field of usefulness of yohimbin in ophthalmic practice are as follows:

Two per cent. Solution of Yohimbin.—Right eye of Dr. J. H. Claiborne. 12.22. Two drops of yohimbin in right eye; slight stinging. Astringent feeling similar to cocaine; stinging; passed in two minutes. 12.24. Two drops; stinging slightly less; eye slightly red; stiff sensation similar to that produced by cocaine; no difference in size of pupil. 12.27. Distinct insensibility of cornea and conjunctiva; two more drops; stinging less than ever; no increase in palpebral fissure. 12.32. Insensibility slightly wearing off; eye quite red; slight fear of light. 12.37. Anesthesia very faint; eye red, uncomfortable; stiff feeling wearing off; no difference in pupil. 12.45. Anesthesia gone; redness still persists. 1.15. Redness still; eye comfortable.

From the above experiment, it will be seen that two drops of a two per cent. solution of yohimbin-spiegel introduced into the conjunctival sac of a normal eye, twice, at intervals of two minutes, will, in five minutes from the initial instillation, produce a corneal and conjunctival anesthesia which lasts about five minutes. It also produces redness, lacrimation and causes the stinging sensation and the stiff feeling characteristic of cocaine. No widening of the palpebral fissure was observable.

Two per cent. Solution of Yohimbin.—Right eye of James Buckley. 11.15. Three drops into right eye; redness, stinging, flow of tears. 11.17. Three drops; stinging less. 11.19. Scarcely any stinging. 11.21. Three drops, no stinging, tactile sensation, conjunctiva; perfect anesthesia of cornea. 11.23. Three drops, no stinging. 11.25. Three drops into conjunctiva; tactile sensation; cornea as before. 11.30. Cornea as above, apparently absolute anesthesia of conjunctiva. 11.40. Same as before. 11.45. Cornea as before; conjunctiva slightly sensitive, pupil slightly dilated, vision slightly blurred for far and near: tension normal. 11.50. Conjunctiva as before; cornea as before. 12 M. Cornea and conjunctiva as before; pupil normal; vision normal. 12.10. Sensation of cornea slight; conjunctiva distinctly sensitive, eye quite red. 12.30. Very faint sensibility of cornea. 1 P.M. Normal sensibility, slight redness.

From the above it will be seen that six instillations in ten minutes of a two per cent. solu-

[1] Received for publicaton February 2, 1904.

tion of yohimbin will produce an anesthesia of the cornea which persists as complete anesthesia for thirty-five minutes after the last instillations, and disappears completely only at the end of an hour and a half. The conjunctiva obviously becomes sensitive a short time before the cornea. The first instillation was made at 11.15, and the sixth and last one at 11.25. At 11.45, half an hour after the first instillation, there was a moderate dilation of the pupil and slight blurring of the vision for far and near. At the end of fifteen minutes, the pupil was normal. It was again observed that the cornea remained sensitive longer than the conjunctiva.

The idea of combining yohimbin and adrenalin chloride, to study the effect, presented itself. Accordingly equal parts of yohimbin in two per cent. solution and adrenalin chloride solution were mixed in a clean dish and the following experiment was made:

Mixture of Adrenalin and Yohimbin.—Left eye of James Buckley: 11.41. Three drops of above solution in left eye. Stinging about same as yohimbin alone. 11.43. Three drops; less stinging. 11.45. Three drops, scarcely any stinging; redness about the same as yohimbin alone. 11.46. Cornea insensible; conjunctiva slightly so. 11.47. Three drops. 11.49. Three drops. 11.51. Cornea absolutely insensible; slight sensation to touch on conjunctiva. 11.53. Three drops; no change in pupil. 11.55. Three drops. 12.01 (twenty minutes). Anesthesia of cornea complete; conjunctiva has slight tactile sensation. 12.03. Pupil commencing to dilate particularly for distance, less for near. 12.06. Corneal anesthesia, conjunctiva, tactile sensation, pupil still dilated, accommodation apparently unaffected, temperature normal. 12.11. Corneal anesthesia, conjunctiva, tactile sensation, pupil same, no apparent effect on the accommodation; eye as red as yohimbin alone. 12.16. Faint blurring of sight for distance and near; pupil quite large for distance, but reacts considerably for light and reading. 12.21. Corneal anesthesia complete; conjunctiva slightly painful, very red and suffused, but no worse than with yohimbin used alone. 12.26. Corneal anesthesia complete; conjunctiva slightly sensitive, pupil normal, accommodation normal. Tension normal. 12.31. Same condition. 12.36. Same. 12.41. Same. 12.46. Cornea slightly sensitive. 1.05. Sensation of cornea not yet perfect, considerable difference between two eyes. 1.22. Both corneas same. 2.15. Congestion gone.

Observe that six instillations were made in fifteen minutes. The complete corneal anesthesia persisted from 11.55 to 12.41, or about forty-five minutes; again, the conjunctiva regained its sensitiveness sooner than the cornea. The pupil commenced to dilate at 12.03, about five minutes after he last instillation, and persisted till about 12.26, having lasted about twenty minutes. There appeared to be a faint blurring both for far and near during the entire time. The redness caused by the instillations was quite as marked as by yohimbin alone, and at no time was there the faintest sign that the characteristic effect of adrenalin on the conjunctiva and eye-ball was present. The anesthesia of the cornea was profound, and the anesthesia of the conjunctiva while present was never so marked or startling as that of the cornea.

The writer has not used either yohimbin alone or in combination with adrenalin in any operation on the eye requiring local anesthesia.

The following conclusions are justified from the above study:

1. A two per cent. solution of yohimbin-spiegel, either alone, or in equal mixture with adrenalin chloride solution, dropped into the conjunctiva cul-de-sac from five to six times in ten or fifteen minutes, will produce both corneal and conjunctival anesthesia. Marked anesthesia of the cornea lasts from thirty to forty-five minutes after the last instillation; the conjunctival anesthesia is at no time so profound as the corneal, and disappears several minutes before the latter.

2. There is a slight stinging sensation immediately following the instillation which becomes less and less with each instillation, finally disappearing altogether.

3. The eye becomes immediately suffused and continues red for more than an hour after the last instillation.

4. There is no widening of the palpebral fissure.

5. There is a moderate but marked dilatation of the pupil which comes on several minutes earlier after the last instillation with adrenalin and yohimbin in combination than with yohimbin alone, but lasts in either case from fifteen to twenty minutes.

6. The slight blurring of the vision for far and near appears to be due to spherical aberration rather than to paresis of accommodation.

7. Yohimbin alone or in combination with adrenalin, is an exceedingly mild mydriatic.

8. Adrenalin when mixed in equal parts with yohimbin in two per cent. solution, loses its constricting power upon the blood vessels of the palpebral and bulbar conjunctiva.

9. This last-mentioned fact suggests the idea that yohimbin may be an antidote to adrenalin chloride.

10. In view of the congestion caused by yohimbin, it cannot be considered the ideal anesthetic for operations involving the conjunctiva or muscles.

11. As an anesthetic in cataract extractions and in iridectomy, it would probably be effective.

12. On account of the congestion produced by it, yohimbin would be inferior to cocaine as an anesthetic in all operations upon the eye.

Ear, Nose and Throat.—Haike (*Therapie der Gegenwart,* May, 1903) made use of yohimbin solution and found it useful in ear and nose work for the removal of the nasal turbinals and granulations, and of polypi from the ear, because of its freedom from toxicity and because it did not cause the tissues to contract (as cocaine does) and so render it difficult to remove them.

Before making use of yohimbin in operative work it seemed advisable to ascertain some of the peculiarities of the alkaloid, so some preliminary experimental work was done by Dr. Coburn as follows:

In general it may be said that a two per cent. solution of yohimbin appreciably benumbs the mucous membranes in two minutes, in five minutes they are markedly anesthetic and in ten minutes the maximum degree of anesthesia with this drug is obtained. Anesthesia lasts from one-half to three-quarters of an hour and then sensation, gradually returns, being completely restored in one hour and a half. As yohimbin does not act on cutaneous surfaces except by injection (directly affecting only mucous surfaces) it could only be applied in such cases where there was perforation or destruction of the membrana tympani or where there were granulations or polypi.

In the nose its application to the turbinals seemed at first to produce a temporary swelling with considerable hyperemia, after which there was some contraction of the tissues, though the redness persisted to the end of the experiments.

Applied to the tonsils, uvula, and pillars of the fauces there was little change noted except perhaps a slight flushing.

Salivation was quite marked at first followed by a sensation of dryness. There was no puckering or constricted feeling such as occurs after the use of cocaine in the mouth. The solution is only slightly bitter.

Mixed with equal parts of adrenalin chloride, one to 1,000, and applied to the turbinals, there was considerable contraction of the tissues, not so marked as with adrenalin alone but much more so than with the yohimbin solution alone. The characteristic blanching of the tissues peculiar to adrenalin was wanting, as was also (with the mixed solutions) the peculiar redness caused by the application of yohimbin alone.

Compared with cocaine, the pallor, anesthesia and contraction of the tissues were not nearly so pronounced.

For the examination of the nose, the determination of spurs and differentiation of hypertrophies from simple swellings it was not as effective as cocaine because the contraction caused by it was not so marked.

To anesthetize the nares for the introduction of the eustachian catheter it was sufficiently effective, but where hypertrophied turbinals were obstructive, cocaine was preferable. Nasal spurs and hypertrophied turbinals were removed during the anesthesia produced by it, but sensation was not so thoroughly obtunded as with cocaine while the immediate hemorrhage seemed unusually severe and lasted for some time. On this account some of the patients were rather frightened at the loss of blood.

Hemorrhage was not sufficiently severe to require plugging.

Secondary hemorrhage did not occur.

Cauterization of the tonsils to which yohimbin solution had been applied was rather painful.

Amputation of the uvula caused some pain and the oozing of blood was considerable for some time. A peritonsillar abcess was incised under cocaine anesthesia with considerable pain; a second opening on the following day was necessary and this was performed under yohimbin anesthesia with much less pain than the first time.

It is a well-known fact that cocaine does not readily or thoroughly anesthetize inflamed tissues, and it may be that yohimbin has not this peculiarity, but acts well on both normal and inflamed surfaces. This is a point requiring further testing.

REMARKS.

Before yohimbin is extensively used its effect on germ life should be determined: whether like cocaine fungi and germs can grow in its solution or whether like holocaine it is slightly antiseptic.

The question of sterilizing the solutions also arises because of its rapid deterioration in solution; boiling will probably hasten the process.

Because of the hyperemia which yohimbin causes its use in persons with hemorrhagic tendencies may be dangerous. Whether it produces hyperemia in distant organs or mucous membranes when injected also requires determination.

Cocaine occasionally causes sexual excitement; whether in view of its aphrodisiac power yohimbin will do this in the quantity and strength used, especially when employed in the mouth and throat, requires extended observation.

ADVANTAGES.

Non-toxic.
Long duration of anesthesia.
Does not markedly contract the tissues.
Taste only slightly bitter.
Does not cause unpleasant contraction of throat and mouth.

DISADVANTAGES.

Does not keep well.
Does not contract the tissues.
Hyperemia and hemorrhage after operation.
Salivation.

PROGNOSIS AND TREATMENT OF URETHRAL STRICTURE.[1]

BY EDWARD L. KEYES, JR., M.D., PH.D.,
OF NEW YORK.

SURGERY differentiates itself from medicine by the act of man. Whereas the physician must usually wait upon nature and assist the patient to recovery by forestalling complications and strengthening him to overcome an inevitable foe, it is the privilege of the surgeon to open hostilities.

Such being the case, it is essential in debating the prognosis of a surgical disorder—and urethral stricture is essentially a surgical disorder—to deal intimately with its treatment. The two are inseparable. Proper treatment of stricture implies, in general, a good prognosis; improper treatment, a bad prognosis. Indeed, we may go

[1] Received for publication March 22, 1904.

even farther and state, with ample justification, that proper treatment of the causes of stricture will prevent its occurrence.

The causes of stricture are two: Gonorrhea and trauma. Let us begin by considering the prognosis as to stricture in these conditions.

The opinion prevails that stricture is usually caused by chronic gonorrhea. No doubt this opinion is founded on the fact that chronic gleet usually precedes and accompanies other symptoms of stricture. But closer observation reveals the fact that many cases of chronic gleet go on for years without producing stricture; while, in the other cases, the gleet is itself the first symptom of a gradually contracting stricture. After all, stricture is nothing more than a scar; and gonorrheal stricture is usually a dense and deep-seated scar founded, the pathologists tell us, on inflammation about the glands and follicles of the urethra. It is obvious that the intensity of this perifolliculitis depends on the intensity of the urethral inflammation against which it reacts. In other words, it is the acute stage of gonorrhea, with its blood, ardor and chordee, that lays the foundation for future stricture; and to prevent stricture we must modify the acute stage of the specific cause. This is one of the important advantages of the so-called abortive treatment of gonorrhea. I have employed this treatment for more than three years and have never known stricture to follow its use.

Traumatic stricture is attributable to two causes: Urethral instrumentation and perineal injury. Happily, the day of urethral brutality is almost past. The practice of "burning out a clap" with copious and concentrated silver nitrate, and of tearing the canal with metal instruments of all sizes and shapes, is no longer the ornament of modern surgery.

The sensitiveness of the urethra is respected more than it used to be; but be as gentle as we may, there is one condition in which the use of an instrument sometimes causes stricture. I refer to the constant passage of a catheter required by many cases of prostatic hypertrophy. Some of these patients acquire stricture in spite of every precaution; but, fortunately, this stricture is superficial and soft, readily yielding to dilatation.

Quite the opposite is traumatic stricture due to perineal injury. The patient falls astraddle the edge of a plank or some sharp object. Hemorrhage from the urethra, difficult urination, even complete retention, disclose the urethral injury, and stricture follows swift and sure—stricture of the most resilient, intractable type. Indeed, so dense is the scar that follows an almost trivial injury of this kind, that the only safe practice is to perform external urethrotomy in every case, be the symptoms of urethral rupture ever so mild, and to minimize or prevent dense scar formation by incising the contused canal and draining with a large perineal tube. Stricture will doubtless ensue, but it will be relatively benign and dilatable.

So much for prognosis before the fact. When stricture is actually present the immediate prognosis depends entirely upon its dilatability. If the passage about twice a week of conical sounds or bougies causes a gradual widening of the caliber of the urethra, so that at each session larger instruments will pass without the use of too much force, the prognosis is excellent; the patient appreciates the prompt subsidence of symptoms, and the surgeon recognizes the gradual absorption of the scar. But the stricture may be undilatable for one of four reasons: it may be resilient, irritable, impassable or complicated.

Resilient or unyielding strictures are those which do not yield to dilatation, which after each passage of a sound, recontract to their former tightness. Such strictures are common in the penile portion of the urethra. In this region we frequently meet a stricture that yields to dilatation up to a certain point, but beyond this is persistently resilient. This fact once established, internal urethrotomy is demanded. The urethra should be cut widely upon the roof; then the occasional passage of a sound will maintain the caliber of the canal.

In the deeper urethra resilient strictures are usually, perhaps, always, traumatic. Gonorrheal strictures of the bulbous portion of the canal—be they ever so dense—are doubtless always dilatable, unless the tissues have been damaged by brutal surgery or by periurethritis and urinary infiltration. Not so traumatic strictures: these involve the membranous urethra, and are often so dense and resilient that nothing short of perineal section and excision of all the scar tissue will effect a cure. In order to be radical such an operation may require the removal of an inch or more of the canal and the application of a skin graft to fill the gap; yet it is always wise to resort to operation at once rather than to temporize with resilient deep stricture, vainly hoping that it may become dilatable.

Irritable stricture does not resist dilatation, but resents it. Every passage of a sound, in extreme cases every kind of urethral application whatsoever, arouses acute inflammatory reaction in the form of urethral chill, acute prostatitis or swelled testicle. In face of such an explosion local treatment must stop, and when similar outbursts follow every attempt at dilatation, it is impossible to make headway. In order to overcome this difficulty two courses are open, the one, mild, slow and uncertain, the other radical, but relatively dangerous. If circumstances permit, the palliative course is to be elected. Local treatment is stopped and internal treatment pushed. Antiseptics, such as urotropin, salol and methylene blue; sedatives, such as liquor potassæ, tincture of hyoscyamus, codeine and the bromides; balsamics, such as sandalwood and wintergreen oil, with hot sitzbaths and, if necessary, suspension, guaiacol and poultices to the testicle, constitute the treatment: for the stricture irritability is not a quality of the stricture itself, but a manifestation of smouldering prostatitis, vesiculitis or

pyelonephritis, which inflammations must be controlled by the above-mentioned remedies before local treatment of the stricture can profitably proceed.

But such a course may fail to effect its object, or the retention or sepsis due to the stricture may be so grave as to threaten life. No alternative is then possible; external urethrotomy must be promptly done. The risk of operation under such circumstances is not small, especially since the emergency often arises in cases that are worn out by suffering and sepsis, fatty in heart, sclerotic in kidneys, utterly unfit for surgical shock. Whatever delay is permissible should be made use of to improve the patient's condition by milk diet, saline enemas and urotropin to the limit of tolerance, and the operation itself must be rapid perineal section with drainage by a large perineal tube. When relapsing epididymitis can be relieved by no other treatment, the vas deferens may be cut and tied. This prevents relapse, renders the testicle sterile, but affects neither the appearance of the gland, nor the potency of its possessor.

Impassable stricture, the third variety of undilatable stricture, is of purely negative interest. If actually impassable perineal section without a guide is our sole resort; but it is a great delight—albeit a tedious performance—to pit one's dexterity against the tightness, or rather the tortuosity, of such a stricture. Tight it certainly is; yet the reason why a filiform bougie sometimes fails to enter a channel from which urine will flow in measurable stream, is because the tortuous passage transmits fluid, but will not unbend to permit the entrance of a stiff instrument. Now the potent agencies to render a stricture impassable are congestion and spasm—this is exemplified by the occurrence of retention of urine from such causes as exposure to cold and overdrinking—hence the first effort to enter such a stricture must be, not a brutal and irritating prodding with bougies, but a systematic reduction of congestion and spasm. If the occasion permits, let the patient have a hot hip bath, an injection of morphine, even a course of balsamics and sedatives. Then begin operations by distending the anterior urethra with a solution of cocaine, 5 per cent., and adrenalin 1:5,000. Hold this in the canal five minutes, then inject sterilized olive oil; then to instruments. Filiform whalebone bougies, bent obliquely or bayonet-wise, are passed *secundum artem* very gently, until one engages and enters the bladder. The others are then withdrawn, and a small tunneled catheter passed if possible. Considerable force may be employed in this maneuver; for the instrument being guided can not make a false passage, and the benefit from ironing out the tortuous passage more than counterbalances the damage from well measured pressure.

Whether the tunneled instrument passes or not, it is safer to tie the filiform into the urethra for twenty-four or forty-eight hours, at the end of which time tunneled instruments up to 10 or 12 French may probably be passed and progressive dilatation instituted.

One other agent may be useful to overcome urethral spasm, viz., electricity. I have not known electricity to cure stricture or to cause the absorption of scar tissue; but, last year, one of the members of your society, Dr. Hickling, called my attention to the fact, which I have since seen demonstrated by Dr. Chetwood, that very mild electrical currents—five or ten milliampères—will sometimes (not always) relax very tight strictures that fail to respond to any other form of treatment. Such are the methods of avoiding operation in certain cases of tight stricture; methods brilliantly successful in certain instances, but neither practicable nor profitable in others.

The complications of stricture, such as stone, infiltration of urine, periurethral abscess, etc., modify the prognosis of the disease as well as its treatment; but let us pass these by and turn our attention to the more interesting subject of the remote prognosis of stricture. Suppose the patient refuses our treatment, what are his prospects? Or suppose we have successfully dilated or cut the stricture, will it remain well, or will it recur? Such are the questions one must be prepared to answer.

The location of the stricture makes all the difference. If it lies at or in front of the penoscrotal angle, the chances are that it will contract very slowly and will never become sufficiently tight to cause retention. Such a stricture is likely to be resilient and difficult to cure without urethrotomy; yet if once fully dilated, or cut and kept open by sounds for three or four months, a permanent cure may be confidently expected.

But strictures that lie deeper than the penoscrotal angle, strictures of the bulbous urethra and of the bulbomembranous junction, promise a far graver history. If neglected they cause retention with all its horrors, chronic hypertrophic cystitis, dilatation of the kidneys and ureters from back pressure of the urine, pyelonephritis, abscess of the kidney, of the prostate, peri-urethritis, infiltration of urine, epididymitis, and death by urinary septicemia (a combination of sepsis and uremia).

Such strictures if taken in time and dilated by sounds often resolve with marvelous rapidity, in marked contrast to the stubbornness of anterior strictures; but after dilatation the contrast is even greater; for no matter how smoothly the canal is ironed out, no matter how thorough the apparent cure of a stricture in the deeper portions of the urethra, it will almost inevitably relapse. Sooner or later gleet reappears, then dysuria, then retention. The interval of perfect health may be months; it is more likely to be years; but all the while stealthily and unsuspected recontraction progresses until five, ten, twenty years after the passage of the last sound, once again there is retention and the cycle is complete.

In estimating the quality of this utterly bad prognosis for stricture of the bulbous and the membranous urethra, three factors deserve con-

sideration, viz., the nature of the stricture, the thoroughness of dilatation and the duration of treatment.

The nature of the stricture, its density, its extent, its degree of contraction, its gonorrheal or traumatic origin:—all these factors bear upon the ultimate prognosis. The old, dense, tortuous stricture, involving inches of the urethral wall and admitting only a fine bougie, may be expected to recontract after treatment more rapidly and more viciously than a stricture of softer tissue, of larger caliber or of less extent. The difference is measurable in years. For example, traumatic stricture often contracts so tightly as to cause retention within a few months of the injury. Such a stricture fully dilated recontracts with equal speed and a few months more suffice to bring on renewed retention. Gonorrheal stricture moves more slowly. Indeed, the patient with gonorrheal stricture may go on for months, even for years, suffering repeated retentions, relieving these by hot sitzbaths or by an occasional poke with a very fine catheter, and successfully avoiding for an indefinite period any real relief by dilatation or operation. Such a plan of action is, of course, successful chiefly in deluding the patient. It only delays the surgeon—for it can not check the gradual progress of ascending renal infection—and it leads ultimately to perineal section under most unfavorable circumstances, or to death by urinary septicemia; perhaps to both. The struggle may be continued for five or ten years, though it may be shorter. Exceptionally, the very first retention causes infiltration and so requires immediate section.

The interval of relief that follows the dilatation of a stricture depends in part—as we have just seen—upon the nature of the stricture. If treated similarly, traumatic strictures recontract much more rapidly than less fibrous ones. But the element of sufficient dilatation enters very largely into the prognosis. If the stricture is sufficiently dilated, it will not recontract for months or years; if it is not sufficiently dilated, recontraction begins promptly.

What then is sufficient dilatation? This implies two things: (1) That the stricture shall be dilated so widely that it no longer grasps a full-sized sound. This, for an adult, varies from 27 to 32 French; (2) that it shall remain thus dilated for three months. In other words, after the stricture has been dilated to full size by the introduction of sounds at intervals of from three to ten days, the patient is dismissed for a month.

If the full-sized sound then passes readily, the interval is made two months, then three months; then, if all is well, the patient may be assured that his stricture is quite dilated. But he may be equally assured that, no matter how free from symptoms he is during this time, his stricture will surely recontract unless he passes a sound once in six months or once a year for an indefinite period. This course of after-treatment is the only possible assurance of safety. It may be that, after many years of such treatment, the tendency to recontraction will be finally and permanently conquered; but we lack certain assurance of this, and, therefore, are not justified in promising the patient that he will ever be free from the necessity of celebrating New Year's and the Fourth of July in thus calling up old memories.

Such, generally, speaking, is the prognosis of urethral stricture, often grave, always dependent upon proper surgical treatment.

THE SUBMERGED TONSIL.[1]

BY THOMAS J. HARRIS, A.M., M.D.,

OF NEW YORK;

ADJUNCT PROFESSOR OF LARYNGOLOGY, NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL; MEMBER OF NEW YORK ACADEMY OF MEDICINE; AMERICAN LARYNGOLOGICAL ASSOCIATION; AMERICAN OTOLOGICAL SOCIETY; NEW YORK COUNTY MEDICAL SOCIETY, ETC.

The battle has waged long and furiously over the question of the enlarged tonsil and its proper treatment, until, at the end of many years, it can be confidently asserted that we all recognize the evils, present and future, of such growths and the necessity of some form of treatment.

No longer is heard, at least not openly, the assertion so common a quarter of a century ago—that they should be left alone as of no consequence and in time are outgrown by the child.

The writer has no intention of opening these old controversial sores anew, for he believes that they have been definitely healed. It is to a condition closely allied—both etiologically and pathologically—but which is far more liable to be overlooked that he desires to call your attention for a few minutes, *i.e., the submerged tonsil.* What do we mean by it? What symptoms does it or may it give rise to, and finally, what are the most appropriate methods of treatment, if any, to be employed in its correction?

The submerged tonsil is a term used by various writers to describe that form of faucial tonsil enlargement which is in whole or greater part hidden by occluding anterior pillars so that at first sight no excess of growth may be recognized.

The usual enlarged tonsil protruding in the median line is, according to most authorities, a *hypertrophy* or an *hyperplasia.* The hypertrophic form is non-inflammatory in origin and is made up in great part of an increase in the lymphatic element—the fibrous tissue not being conspicuous. The hyperplastic form, on the contrary, is the result of one or many previous tonsillar inflammations, and while there is an increase in all the histological elements, the fibrous reticulum is especially involved. It is this inflammatory hyperplastic form which is found in the submerged tonsil. There has occurred here, or will take place in time, a secondary sclerosis or atrophy. Indeed, the term should not be confined to the moderately enlarged tonsil hidden by the anterior pillar. The atrophy is often so pronounced as to reduce the size of the tonsil—well below normal—and yet give rise to a not insignificant group of symptoms.

[1] Read at the Annual Meeting of the Medical Society, State of New York, held in Albany, January 27, 1904.

Symptoms.—It is important to recognize their significance, for, unless attention is directed to them, they are liable to be overlooked.

Peritonsillar Abscess.—Of prime importance, is a tendency to repeated attacks of peritonsillar abscess. This is easily understood when the nature of these flat tonsils is once recognized. They show marked adhesive bands, closely connecting them with one or both pillars. Often the anterior pillar and the tonsil are so joined as to be virtually one. The tonsil itself contains deep crypts often filled with cheesy, decomposing material. What better soil could be desired for the breeding of germs! These work their way inward and proceed to grow in what is in effect a closed cavity, until in time the purulent product of inflammation forces its way to the surface.

Dr. F. C. Cobb, of Boston, in a recent paper before the American Laryngological, Rhinological and Otological Society, has gone extensively into the situation of these abscesses. As you may recall, the tonsil rests on the aponeurosis of the superior constrictor muscle. It is, however, surrounded by considerable loose areolar tissue. In the course of its development a three-cornered membrane from the anterior pillar appears extending from the velum down toward the tongue where the apex is attached—and backward to the posterior pillar. This encloses a space, at the third or fourth month of fetal life, which is later filled with lymphoid tissue—the tonsil. This membrane is the so-called plica triangularis of His. In the adult it is frequently found reflected over the tonsil. In such cases it is often possible to discover a small fossa above the tonsil formed by the plica—fossa supratonsillaris, which sometimes has the depth of 1½ C. This cavity has the disadvantage of possessing a very small mouth which is easily occluded by adhesive bands. It then becomes, in the event of the entrance of pernicious bacteria, a possible source of peritonsillar suppuration. This situation is, however, rare as compared with the areolar tissue, at the base of the tonsil. This, on account of its looseness and intimate connection with the tonsil, is most easily affected. It is also apparent how at the onset of pus formation, the tonsil will be pushed inward. The presence of the bands of adhesion will tend to prevent natural drainage and indeed to retain all unhealthy secretions. While it scarcely falls within the scope of this paper, the method of incision as advised by Cobb is worthy of mention. He argues, very sensibly, it appears to me, that the failure to locate the pus (as is so often the case in the classical incision made between the uvula and the wisdom tooth), is due to the fact that the depth of the tonsil is not taken into account and so is in reality punctured in place of the abscess.

The abscess is at the outer side of the tonsil and is separated only by a wall of mucous membrane. A probe or narrow bistoury accordingly, carried parallel to the axis of the tonsil and between it and the anterior or posterior pillar, as the case may be, on account of the anterior or posterior bulging, will enter the base of the abscess without difficulty and without risk of wounding any important blood vessels.

Of still more common occurrence are attacks of tonsillar inflammation non-suppurative in character. Indeed such tonsils are most liable to attacks of this nature. Aside from this tendency to quinsy and tonsillitis certain other symptoms are more or less constantly found in connection with the submerged tonsil.

Pain, the location of which is sometimes not definite, but described as in the throat, will often be an annoying and persistent symptom coming on in the form of sore throat. The patient is fond of describing himself as the victim of a "delicate throat." Examination may reveal a well-developed follicular condition on the posterior wall of the pharynx, which will engage your attention without avail as regards success in relieving the symptoms. Often, too, a constant collection of mucus in the larynx is complained of, with difficulty in using the voice, to the extent of even hoarseness or altered quality of tone for speaking or singing.

The Ear.—Occasionally, in the case of extensive adhesions, certain ear symptoms will be present, most common is earache. This is seen by us all in almost every severe case of tonsillitis, showing how close is the connection. The significance of the flat tonsil in catarrhal otitis is less clear. Formerly the writer was wont to disregard it. To-day, we believe it is a causal factor of no little value. If it is borne in mind that the attachment of the muscles known as the anterior and posterior pillars are in close relation to the pharyngeal mouth of the Eustachian tube, it will readily be seen how, in the case of great adhesion of these pillars to the tonsil, all normal movement is restricted or lost. Further, the pressure of the tonsil with its adhesive bands, on the adjacent blood vessels running to the nasopharynx and Eustachian tube must of necessity interfere with the proper blood supply of those parts. This alteration of function can scarcely fail to result in a chronic inflammation which is bound to extend itself sooner or later into the nasopharynx and thence to the Eustachian tube. Certainly, whatever is the true explanation, it is in our judgment a wise step to remove, not merely adenoid growth in the nasopharynx, but also to separate and remove a like condition in the fauces.

Cough.—Cough is at times a most annoying symptom. It is without expectoration, has possibly existed for months and defies all internal medication. There is often an associated dyspepsia, with coated tongue and inactive bowels, or in place of these more special symptoms, there may be only the complaint of a full and disagreeable sensation in the throat. Finally, before leaving this question of symptomatology, we would like to refer to the significance of the condition in children. In recent months, the proposition has forced itself more and more upon the writer that the average tonsillotomy is an incomplete opera-

tion. As physicians, we have been in the habit of removing any excess of tissue which is present and then desisting. The case passes out of our sight, but in after years returns or presents himself to some other physician, complaining of quinsy or some of the other symptoms just enumerated. Or, possibly, he develops a diphtheria. As a result, the lay or professional mind is led to the conclusion that the tonsillotomy was without value. What now is the true explanation? It is that the operator has removed only a part of the disease. He has left an abundant soil for further infection in the portion of the tonsil remaining hidden by the pillar. It is now the invariable rule of the writer to strive to remove the tonsil as thoroughly as possible, and, before all, to secure a separation of all adhesions.

Treatment.—Whatever may have been the sentiment of the profession a few years ago toward a laissez faire policy in the treatment of the enlarged tonsil, to-day we may confidently assert that such a course is never heard to be advocated in public. All laryngologists, at all events, are agreed as to the necessity of treatment of an active nature. Whatever is said in favor of such a course of treatment to ordinary tonsillar enlargements, applies with double weight to the submerged tonsil. The treatment is essentially surgical; all medication is of no avail. The surgical procedures are (1) a freeing of the adherent anterior pillar, and, if necessary, the posterior pillars; (2) the removal of the tonsil in whole or in part.

(1) The freeing or separation of the adherent pillar is an indispensable step in the operation. Without such preliminary release, any proper attack of the tonsil itself is impossible. In addition, wounding of the pillars is almost certain to give rise to troublesome hemorrhage and great subsequent pain. It will often be necessary, however, to cut loose the plica triangularis in order to free the gland.

Properly performed, the entire operation is scarcely at all painful. Our method is, after cleansing the tonsil and throat with a solution of Dobell, to paint both tonsils with a ten per cent. solution of cocaine. Usually, we operate on only one tonsil at a time, but occasionally we can complete the double operation in one sitting. The painting with cocaine, repeated several times for three minutes, is followed by the injection of 10 to 15 m. of one-half to one per cent. solution into the tonsil. On account of the numerous lacunæ a large part of the solution runs out. We have never seen any bad effects following its use. The employment of stronger solutions as four per cent., reported by one writer, is in my judgment dangerous and to be condemned.

The field prepared, the first and important step in the operation is now to be performed. For this purpose, Pynchon advises, as indeed he does for the entire operation, the use of cautery knives. With these I have had no experience, and so cannot speak with authority. For several years I have employed for slight adhesions the dull hook or separator of Pond, or for more extensive agglutination, the sickle-shaped knives of Leland. Care must be exercised in doing this, or in the case of an atrophied pillar the knife may buttonhole instead of cutting down. At times the released pillar can be drawn back with a fine tenaculum and the exposed tonsil removed en masse with a tonsillitome. Some surgeons find the snare, either cold or electrically heated, very applicable, and even the Volsella forceps and bistoury will at times be found suitable. With all these measures I have had little experience. Occasionally excellent results will be accomplished without any removal of tissue by merely opening up and thoroughly curetting the various diseased crypts. For this, ingeniously designed angular knives have been devised. My own preference is, however, for as complete a removal of the diseased tonsil as possible, and for this purpose I know no instrument equal to the tonsil punch. Various models have been suggested, but those of Myles seem best suited, especially the new right and left angular variety. The chief concern is to avoid cutting the tonsil pillar, the risk of doing which is greatly reduced with the new instrument. With the punch the danger of hemorrhage is avoided. The work can be done rapidly, five to ten minutes sufficing for the actual cutting. The subsequent reaction and soreness is surprisingly slight. The patient is sent home, with orders to remain indoors and gargle frequently with a hot saline solution. For the pain and discomfort I have found orthoform, in the form of an emulsion, or five-grain tablet works admirably. The other tonsil can be removed the following week.

117 East Fortieth Street.

PSEUDOBULBAR (GLOSSO-PHARYNGO-LABIAL) PARALYSES.[1]

BY LEONARD K. HIRSHBERG, A.B., M.D.,
OF BALTIMORE;
ASSISTANT NEUROLOGIST, COLLEGE OF PHYSICIANS AND SURGEONS.

In 1872 Joffroy showed that the symptoms of bulbar paralysis could be present with anatomical changes demonstrable only in the cerebrum. In the same year Jolly reported a case with symptoms of bulbar paralysis and multiple sclerosis. On autopsy, foci of scleroses were found in the lenticular nucleus, but none were present in the pons and medulla.

Two additional cases were reported in 1877 by Lépine and von Barlow. Lépine first gave the name pseudo glosso-pharyngo-labial paralysis to this condition. After this in quick succession cases were published by Eisenlohr, Féré, Berger, Ross, Quincke and Oppenheim and Siemerling. The latter authors published five additional cases in 1886 and reviewed the literature. Since then cases have been described with various unusual phenomena by Goldscheider, Gaavielle, Barchard, Senator, von Leyden, Otto, Colman, Ritaman, Magnus, Kirchhoff, Bamberger, Wollenberg, König, Brauer, Ganghofner, Hartman,

[1] Presented before the Maryland Medical and Chirurgical Faculty, February 19, 1904.

Polenero, Perwuschin, Variot and Roy, Perritz, Bernhardt and Perrero. I have been unable to find any case reported from America.

The symptom complex of pseudobulbar paralysis is founded upon various disease processes. Slowly developing degenerations of the motor nerve nuclei in the floor of the fourth ventricle account for true or Duchenne's bulbar palsy. Atrophy of the anterior horn cells and sclerosis of the pyramidal tracts are the pathological findings which manifest themselves in an amyotrophic lateral sclerosis with progressive muscular atrophy.

A polioencephalitis with degenerations in the cortical nuclei may develop rapidly and even then go on to repair. It would therefore make the existence of disease in the medulla probable, and a subacute poliomyelitis of the cord less important. A disease of the medulla analogous to this is described as a pseudobulbar paralysis occurring in children (Eisenlohr and Berger).

Still another group of cases are those with independent disease of the bulbar nerves of peripheral origin, a bulbar neuritis.

Quite different from any of these just mentioned are the cases of acute apoplectic bulbar paralyses. Their pathological picture shows hemorrhagic foci in the bulb and especially the consequent softening. Effusions of blood into the pons are by no means unusual events, but owing to the sudden death which they cause, they rarely give rise to bulbar paralyses.

Arteriosclerosis is the most constant etiological factor of acute bulbar paralysis, a form quite as common as the luetic endarteritis. Disease of the vessel walls followed by thrombosis and softening of the tissues is the sequence. Rarely emboli are carried to the cerebral vessels in endocarditis. The vertebrals and basilar are those most commonly affected, and obliterated arterioles must be most carefully searched for. This is particularly true of the arterioles supplying the pons, medulla and neighboring nerves. A case of Schultze's showed miliary aneurisms of the arterioles. Griesinger's and Moeser's cases were similar. A pressure atrophy of the neighboring parts was also present, besides diseased foci in both hemispheres near the lenticular nuclei, internal and external capsules and corpus striatum.

Hemorrhages, apoplectic cysts, areas of softening and sclerosis, may be found, occasionally disposed symmetrically. The cases reported by Magnus and Kirchhoff, in which lesions were discovered only in one hemisphere of the brain and showing clinically distinct pseudobulbar symptoms are discredited by Oppenheim, who contends that if serial sections of the opposite hemisphere had been thoroughly examined under the microscope, lesions would have been demonstrable.

With regard to the differential diagnosis: True (or Duchenne's) progressive bulbar palsy usually develops gradually, with continuous muscular atrophy and shows marked electrical changes, with fibrillary tremors, paralyses of the adductor muscles of the larynx, and death within one to three years, the mind remaining clear to the end.

Speech defects may result from paralysis of the palatine velum after diphtheria but can always be differentiated. Confusion may arise from the benign form of polioencephalitis in children which resembles the bulbar paralysis. Atrophy, however, is always present.

Myasthenia gravis with asthenic bulbar paralysis resembles pseudobulbar-paralysis very closely. This disease tends to recover. It is really a neurosis with no anatomical foundation. The ocular muscles are usually involved. But the most important symptom is the rapid exhaustion of the affected muscles by the Faradic current, yet still reacting to the will.

Pseudobulbar paralysis, an example of which I desire to show you, is marked by the apoplectic onset, absence (or asymmetry) of atrophy hemiplegia, diplegia or paraplegia, are present. The disease is remittent in progress, exhibits normal electrical reaction, cerebral disturbances, dysphagia, aphasia, and at times trismus. The cerebrobulbar form shows marked arterio-sclerosis and many cases have a luetic history. Mental phenomena are always present. Facial paralysis, hemianopsia, lip, tongue and oscular muscle paralyses occur. The extremities are involved, involuntary laughing and crying occur. The palate reflex is often lost. Dyspnea, dysphagia and increased pulse rate are at times present. It develops quite definitely after two distinct hemiplegic attacks often months apart.

In their five cases, Oppenheim and Siemerling carefully studied the entire nervous system by the most improved methods. In addition to the changes in both hemispheres, they found minute diseased areas in the pons and medulla, which had entirely escaped their observation in gross examination.

The pathological findings are first and most frequently arteriosclerosis, especially of the basilar vessels, often accompanied by dilatations and aneurisms. Diseased foci are constantly present in both hemispheres, the internal capsule, corona radiata, basal ganglia and rarely in the cortex, especially over frontal and placental lobes.

Grossly the pons and medulla very rarely show any diseased areas. Microscopically, however, —Oppenheim and Siemerling were the first to point this out—with care and thoroughness in a search of serial sections, the pons and medulla will surely show somewhere areas of sclerosis or softening. These foci are circumscribed and most often found in the transverse fibers of the pons (except the secondary degenerations), in the pyramidal tracts, the lemniscus, in the neighborhood of the fibers of the facial, and at times in the floor of the fourth ventricle.

A critical review of all cases in the literature indicates that the great majority which were completely studied show these minute lesions in the bulbar centers and in the sclerotic basilar vessels. The cases which do not demonstrate such foci, were for the most part insufficiently investigated.

In Léjune's cases the lesions were confined to the pyramidal fibers. Aneurisms in the basilar and left vertebral were demonstrable in Berger's case and some flattening of the pons. In another, atheroma of the basilar vessels and a lesion the size of a cherry seed near the exit of the trigeminus was observed. Eisenlohr's and Ross' cases showed somewhat similar conditions. Ochs in his inaugural dissertation concludes an otherwise finely described case by saying "Microscopic study of a preparation of the medulla, hypoglossus, vagus and accessorious showed no signs of degeneration." Thus demonstrating the incompleteness of his work.

A great number of cases reported as acute bulbar paralysis, have besides the bulbar disease lesions in the cerebrum, and the conviction is reached that the mixed cerebrobulbar glossopharyngo-labial paralysis is an especially frequent form of bulbar paralysis of apoplectic origin.

In two cases reported, Oppenheim and Eisenlohr's, atrophy of the extremities occurred. In spite of this complication of muscular atrophy with contractures and paresis and acute bulbar symptoms, a confusion of the condition with amyotrophic lateral sclerosis was impossible. In Eisenlohr's case the muscular atrophy of the upper arm was directly traceable to a circumscribed lesion due to disease of a basilar vessel. Optic atrophy when present is a point against true bulbar paralysis.

An important difference between the acute forms is the absence of atrophy in the pure cerebral form. Occasional occurrence of psychic disturbances, aphasia, hemianopsia, all indicate this

Difficult respiration and various respiratory disturbances do not occur in the pure cerebral form.

One of the Oppenheim-Siemerling cases is of especial interest. It was one of apoplectic bulbar paralysis with acute onset, developing in the course of five years remissions and exacerbations. Besides the paralysis of the extremities with contractures and exaggerated reflexes on all sides, there were paralyses of the facial, hypoglossus, vagus, spinal accessory, and difficult respirations with high temperature at times. On section the left vertebral showed an aneurismal dilatation, which was so considerable that a corresponding impression myelitis was left in the pons and medulla. The microscopical investigation of serial section showed most of the lesions in the pyramidal fibers. From these the process continued through the raphé, destroyed parts of the olivary bodies and injured the hypoglossal nuclei.

REPORT OF CASE.

J. P., white, male, aged thirty-eight years; occupation, clerk; was admitted to my clinic at the Baltimore City Hospital January 20, 1903, complaining of "bad locomotion." His parents were dead; cause unknown. There were no nervous diseases, tuberculosis, alcoholism or cancer in his family as far as he knew. Personal history showed measles as the only disease of childhood. Had been very bright at school. Gonorrhea twice. Alcoholic history very definite. Three years before admission patient had a hard chancre, followed by general secondary symptoms such as eruption, alopecia and mucous patches. Present illness began with an apoplectic stroke one year before. There was no loss of consciousness. His arm and leg were paralyzed, from which he partially recovered. Last month a second apoplectic attack occurred with loss of consciousness. He remained in bed almost to the time of his appearance at the clinic. Since this attack, he has been unable to walk well, use his arms successfully or speak in his proper tone of voice. He expresses himself with difficulty and catches himself laughing without any reason for it. At times he cries, being entirely unable to control himself and with no grounds for it. His memory is bad and he has much difficulty in swallowing and breathing regularly. He has no frequency of micturition, no dribbling and no loss of control of bladder or rectal sphincters. Notices no odd sensations, no formication, girdle sensation or flushings. He has suffered no pains; sleeps well at night and has normal appetite. Has never noticed any diplopia except when intoxicated. Is not suspicious of his neighbors or surroundings, has no odd dreams, sees or bears no false images. Does not hear voices or see "things."

Physical examination shows a well-nourished, plethoric individual with a strange articulatory disturbance of the character of a bulbar speech. There is a strong, nasal, forced tone, evidently due to a paresis of the palate.

Partial paralysis of the seventh nerve is present. The soft palate is paralyzed, as is also the tongue. There is no atrophy and the muscles respond well to the faradic current. There is a chin clonus, and some weakness of the masseters. Ophthalmoscopic examination is negative for neuritis or atrophy. The pupils are irregular, the left more dilated than the right. Lateral nystagmus is present. The perimeter shows no limitation or contraction in the field of vision. Upon laryngoscopic examination there seems to be some sluggishness in the action of the adductors. Dyspnea is present and the patient occasionally indulges in uncalled for laughter. The superficial arteries show very slight hardening. The pulse is of good tension, regular and 90 to the minute. Test words and sentences elicit no loss of memory or elision of syllables. There is some apathy and deficiency of concentration. He is well-nourished and has what Dr. Osler calls a Bardolphian fascies (hyperemic). There is a diplegic condition of both arms and legs, with contractures of the flexors of the forearm and hand and double pes equino varus. The deep reflexes of the upper extremities and the lower are very markedly exaggerated with a supinator clonus in the right arm and a bilateral ankle clonus. Babinski's reflex is present on both sides. There are no demonstrable sensory phenomena. Hemoglobin 85 per cent., r.b.c. 4,300,000 and leucocytes 6,500. Secretions show nothing unusual.

THE RATIONAL VS. THE "REGULAR" TREATMENT FOR TYPHOID FEVER: HANNA'S CASE, AND SOME OTHERS.

BY CHARLES E. PAGE, M.D.,
OF BOSTON, MASS.

THERE was nothing peculiar in the case of Senator Hanna, either as to the treatment or the result of the treatment, since the case was managed according to the highest art of forced-feeding and drugging, and the outcome was the same as happens in about fifty thousand cases of typhoid fever in this country every year. It is estimated that about 300,000 cases of this disease occur yearly in this country. Of these, 50,000 are killed outright, and the balance, though surviving, are still so depleted in physical stamina that fully one-fourth of those who are said to recover finally die of consumption, as we are told by the life insurance statisticians, whose business it is to know about it.

It is proper for us to remark here that out of the 50,000 fatalities, about 15,000 of the patients *had a right to die!* That is, about five per cent. of all cases of typhoid fever are, from neglect or one or other cause, so deeply diseased that even the highest skill would not avail to save them. That this is a liberal estimate is shown by the following statement of fact, relating to the practice of Drs. Brand, Jürgensen and Vogel, of Stettin, Germany. These gentlemen, some years ago, gave the history of 1,223 cases of typhoid fever, from hospital and private practice, treated by the "Brand bath" method (after the method employed by the late Dr. Ernest Brand), with only twelve deaths, one per cent. And we learn, furthermore, that of these twelve deaths, *not one occurred in any case that came under treatment before the fifth day of illness!*

The treatment employed consists in placing the patient in a tub bath to the ears, the temperature of the water at about 66° F., every three hours or so, when his temperature reaches 103° F. A heavy cold compress is placed over his head before he enters the tub, and during all the time in the water brisk hand-rubbing is given by the attendant, the patient helping in this, if able. The bath lasts about fifteen minutes, and the patient is placed back in bed, dripping, between the sheets, and is well blanketed and given some degree of rubbing and squeezing through the bedcovers if needed to restore comfortable warmth.

Forced feeding is not practised; that is, the patients above referred to were not forced to take any nourishment unless they felt a desire for it. But strict therapeutic fasting was not employed; had it been, it is my firm belief that the illnesses would have been shorter, and possibly another life or two might have been saved. In some of the cases as many as 30 and 40 baths were given; whereas, in my own private practice, in which no food of any sort, except water, is ever allowed until the patient is safely convalescent, and actually hungry, I have never, even in the worst cases, found occasion for more than five or six of these full, cold baths; and I have never lost a single case that came early under treatment. In all ordinary cases coming under my care at the onset of typhoid symptoms, I seldom find the full bath demanded; moderate hydrotherapy, as the damp body-bandage, cold compresses, etc., proving all-sufficient.

Even in the full bath treatment to the extreme limit, there is nothing in the least frightful about it, except to the minds of those, in or out of the medical profession, who are unfamiliar with the method. Properly managed, it is even delightful, *on the average,* to the patient, in that, aside from the first shock of the cold, on being taken from his warm bed and placed in the bath, his comfort is promoted; the dry tongue becomes moist; the head symptoms (delirium or partial delirium, headache, etc.) are banished; the parched skin becomes moist; the heart and entire nervous system are favorably affected, and convalescence is shortly secured.

It should be distinctly understood, however, that neither the bath, nor any other water treatment, is ever employed by one who *understands his business,* for the purpose of "downing the temperature" of the patient; but, solely for its effect upon the heart, the nervous system and the skin. The high temperature is in all cases but one of the means employed, so to say, by the animal organism for the elimination of disease-producing matter; it declines and disappears altogether, and the temperature becomes normal in good time, when the all-round treatment is correct.

About twelve years ago, Mr. W. J. U., of St. Paul, Mich., had typhoid fever and was treated by the family doctor by the method employed in the Hanna case. He was critically sick for two months, and he was several months convalescing. When he had been sick two weeks, his little daughter, six years old, came down with the same disease. The doctor doubtless diagnosed the case correctly; but, when the question of treatment came up, the mother, who had been corresponding with me in the interest of the two children, telegraphed me the history of the case and asked me to wire full directions for treatment, which I immediately did.

The little patient's temperature was 104.5° F. With extreme trepidation on the part of both mother and daughter, the latter was placed in the bath, *à la Brand;* but the effects were so satisfactory that the child begged her mother for another a few hours later. She had four tubbings during the first twenty-four hours, and one on the day following; she wore the damp bandage for several days, as follows: two-ply coarse towel wrung tightly from ice-water, with two-ply, same, dry outside, snugly pinned about the body from armpits to hips, the damp folds freshened as often as they became at all hot; meaning, in general, at intervals varying from a half-hour to 2½ hours, as the disease abates.

In the case cited the disease was speedily aborted, and the child was dressed and on the

street, well, within two weeks from the onset of the attack. There was an exchange of ten telegraphic despatches in all, and four letters of directions. There was in this case a fast of six days; she had a small potion of moderately hot water from hour to hour and all the fresh water she desired. This is the true physiologic diet, doubtless, during the progress and duration of all fevers. Under the reverse management, there can be, according to my belief, such a thing as "feeding a patient into typhoid fever"; that is, patients that go through the regular siege of the disease, under the forced-feeding plan, have the alimentary tract so irritated and inflamed, and the system so poisoned from the absorption of putrescent food substances, that the prolonged illness and death, if there be a fatal termination, may safely be attributed to the treatment, rather than to the original disease.

It seems beyond belief that any physician could be found, at this time, who would deny a typhoid fever patient all the water he craved; but, in fact, such an occurrence is not altogether rare. Water is withheld in great measure upon the theory that "large amounts of fluid interfere with the digestion of other and more nutritious food"; but, as Henry has so tritely remarked, under certain conditions there is *no other food that can truly nourish the body*. During the progress and at the height of typhoid fever, as Dr. Henry remarks, "the blood is of a dark, blackish-red color, and is generally obtained by needle puncture of the finger with more than ordinary difficulty," indicating conclusively a deficiency of water. On the other hand, the thickly coated tongue, sordes, and the generally parched condition of the mouth, indicate quite as clearly the utter lack of all the dissolving and preserving juices absolutely essential to the digestion of solid food or any other food but water. To call milk a liquid food seems to me absurd, when it is stated on high authority that the casein of a pint of milk is equal to a good-sized mutton chop, and is vastly more difficult of digestion; yet we know that as much as two or three quarts of milk are swallowed by a typhoid patient in twenty-four hours.

The results of this abuse of food have been vividly portrayed by the late Dr. Jenner, as follows: Twenty years ago, Sir William Jenner, in an address before the Midland Medical Society of Birmingham, England, referring to the vicious effects of forced feeding, said: "I have seen the patient restless, sleepless, his temperature raised several degrees above what it had previously been, vomit, eject a quantity of curd, and at once the restlessness cease, the temperature fall, the skin become moist, and the patient drop into a quiet sleep. All the threatening symptoms vanish with the ejection of the offending material. Or the undigested curds may accumulate in the bowel, inducing flatulent distention, pain, restlessness, and increased febrile disturbance. Under these circumstances I have seen an enema bring away a large vesselful of offensive, sour, undigested, curds. Or, again, the undigested curds may themselves (and this has not been an uncommon consequence of milk diet in my experience) irritate the bowels, and produce, keep up, or greatly increase diarrhea."

Hippocrates was a wonderfully wise man, and one of the wisest things he ever said, as it seems to me, was that it is best to withhold food *during the progress* of all fevers; and therapeutic fasting has from his day to ours been the sheet-anchor of every expert sick-room dietist in all acute diseases.

One other wise dictum from the same source should be borne in mind, viz., that "physic is the hardest medicine for the system to withstand." The fasting patient will shortly have no movements of the bowels; there is a normal closure, so to say, under these conditions. After convalescence is fully established, the condition of the stomach such as to make the digestion of food possible, and the patient hungry enough to take a half-slice of stale Graham bread for "pie" and pronounce it delicious, this will be a good risk. Two or three times a day, after a day or two, he may have a moderate portion of such bread and, say a few stewed prunes; but the bread is to be chewed by itself, not run down with sauce, or any other fluid but saliva. After a few days of feeding, the bowels will get in condition for a natural movement, but they should never be moved with physic; though occasion may arise in which an enema of a few cupfuls of cold water may be of use in stimulating the action of the lower bowel; but this only in case of the presence of waste matters otherwise difficult to expel.

No end of fever patients have emaciated to skeletons during many weeks of forced feeding, and finally died, largely from inanition, when they would have been convalescent by abstaining, early in their illness, from all foods save water for periods varying from one to two weeks. Such patients at times emaciate much faster on feeding than on fasting; in the first instance they are being both *starved* and *poisoned*, there being absolutely no nourishment in putrefying food substances, while the ptomaines resulting from such putrescence are often as fatal as arsenic or other deadly poison. Many and many a time have I seen emaciation lessen, pain made to cease, all bad symptoms disappear, and strength rapidly return to the fasting patient.

I think that I am not making an overstatement when I say that if every patient beginning to be feverish, with lack of appetite, nausea, etc., were treated on the plan herein indicated, the three hundred thousand cases of typhoid fever occurring in this country every year would be reduced to perhaps fifty thousand, and, of these, forty-five thousand would be restored to health after comparatively "comfortable sicknesses." This would mean a saving every year of forty-five thousand lives, a value to the nation of at least forty-five million dollars, while the saving effected by the shortened sicknesses (to say nothing of the saving of vitality to the restored patients) would amount up to many more millions.

There is a lamentable lack of interest among medical men concerning all such studies as are embraced in this paper. The reason of this is not far to seek: the medical schools give their graduates almost nothing in the way of teaching in hydrotherapy, and it is the almost universal practice with their professors and the hospital physicians to feed early and often, as if the question of digestion and assimilation, and not simply swallowing, were not at the bottom of all true feeding. In the discussion following the reading of an essay on Hydrotherapy, Its Scientific Basis, by Professor Putnam, of Harvard University, recently, Dr. Coggeshall insisted that "it is disgraceful that students should be allowed to graduate from our medical colleges with practically no systematic teaching in regard to non-medical therapeutics," and Dr. Rogers remarked jocosely that "medical colleges ought to cease to graduate men who don't know the difference between a Scotch douche and a hot Scotch." Ku smaul writes: "Of hydrotherapy the young physician knows almost nothing. Here is a great gap in the education of our physicians; here is the real cause of their inability to cope with the empirics for the favors of the public." Professor Credé, of Leipzig, states that "if physicians were better versed in these branches, the field of operation of many quacks would be greatly curtailed," which is only another way of saying that many quacks are more efficient in practice than the average regular practitioner, an admission as true as it is shameful.

MEDICAL PROGRESS.

MEDICINE.

Blood in Anchylostomiasis.—As characteristic changes of the blood in anchylostomiasis, C. Honore (*Arch. internat. de Pharmacodyn.*, Vol. 12, fasc. 5 and 6) mentions an increase in the number of eosinophiles with the occasional presence of eosinophile or neutrophile myelocytes, or nucleated reds. The mononuclears and polynuclears undergo variations which are not in proportion to those of the eosinophiles. The percentage of the latter varied between 1.5 and 52. It could not be determined if their number depends upon the number of parasites, the age of the infection or other unknown factor.

Action of Roentgen Rays on Internal Organs.—If animals are exposed to the action of the X-rays, peculiar changes are found in the spleen. The pigment is excessively increased here, the follicles gradually disappear and the cellular elements of the splenic pulp undergo extensive rarefaction. The earliest of these changes, according to H. Heineke (*Münch. med. Woch.*, May 3, 1904) is the disappearance of the follicles; it can already be noticed several hours after exposure and ceases in twenty-four hours with small animals such as mice and rats. The nuclei of the lymphocytes in the follicles break up into fragments and are gradually removed by phagocytes. The same phenomenon may be observed in all lymph-nodes of the body, in the follicles of the intestines and in young animals also in the thymus. In the bone-marrow, the specific cells are destroyed and replaced by fatty tissue. With exception of a slight diminution in the number of leucocytes, the blood shows no change. When larger animals, such as dogs, were employed, the same lesions could be detected. An exposure of a quarter of an hour with a hard tube will suffice to bring about nuclear disintegration within a few hours. If the animals are killed after eight to fourteen days nothing pathological can be detected, which proves that regeneration is equally rapid. It is not at all impossible that the Roentgen rays may behave in a similar manner in man and that they may exercise a distinct therapeutic effect in pseudoleucemia, leucemia, lymphosarcoma and persistent thymus.

Value of Tuberculin Reaction.—That the tuberculin reaction is not infallible in the diagnosis of tuberculosis is clear, from the article of H. Smidt (*Münch. med. Woch.*, May 3, 1904). His technic is as follows: After absence of fever has been assured for several days by four hourly measurements, one mg. of tuberculin in fresh solution is injected, then, after four to five days, five times this amount. In eight cases with positive reaction, tuberculosis was found at autopsy in only five, in three, carcinoma of esophagus and stomach were the sole lesions. In one there was no reaction, yet evident tuberculosis. Despite such small doses and great care in injecting, serious accidents may occur and a latent process may suddenly become active and even lead to a rapid fatal issue. This happened to the author in three cases—one of leprosy combined with tuberculosis, one of incipient apical tuberculosis and one of affection of the serous membranes. A source of error is to be found in hysterical patients; they sometimes react after tuberculin injections and even after injections of plain water.

Chemical Detection of Digitalin.—Two tests are available to determine the presence of digitalin in organs, namely, the purple color developing when bromine is added to a solution in concentrated sulphuric acid and a green color if boiled with phosphomolybdic acid. C. Binz (*Arch. internat. de Pharmacodyn.*, Vol. 12, fasc. 5 and 6) has discovered, however, that a large number of other glucosides, alkaloids, etc., give exactly the same reaction, so that a serious error would be committed if too much reliance were to be placed upon these tests. The physiological test is thus indispensable, though certain alkaloids developing after death may influence the heart in the same way as digitalin.

Effects of the Roentgen and Radium Rays on Cell Division.—That these agents have a well-marked inhibitive effect on division in both animal and plant cells, is the claim made by G. Perthes (*Deutsche med. Woch.*, April 28, 1904). For the purposes of demonstration he selected the developing eggs of *Ascaris*, a round worm which is parasitic in the horse, and was able to show that the X-rays exerted a distinctly harmful effect, independently of whether or not nuclear division had begun. The effect does not appear at once, but comes on later as development proceeds, the latter being characterized by an irregular course and the production of abnormal end products. Analogous results were obtained when the radium rays were employed. Exposures of growing plant roots to the influence of both varieties of rays also disclosed a marked inhibitive action in their growth. The author suggests that the effects are in all probability due to the production in the living cell of substances which damage the chromatin in the nucleus.

Significance of Blood in the Feces.—An extensive series of observations were undertaken by G. Joachim (*Berl. klin. Woch.*, May 2, 1904) for the pur-

pose of determining the presence of blood in the feces in all conditions where a hemorrhage in any part of the gastro-intestinal tract might have been present. The guaiac and aloin tests were both employed. It was found that in all cases where the presence of blood in the stools could not have been explained, the tests were always negative. Even the presence of a slight epistaxis resulted in a positive test, which rarely occurred after a hemoptysis however, probably because in the latter case the sputum is not as a rule swallowed. Among malignant tumors of the alimentary tract, the tests were positive in every instance, the only exception being a carcinoma of the esophagus. The hemorrhage was regular but always weak. In contrast to this were the cases of gastric ulcer, where positive results were secured in over 80 per cent. of cases, but where the bleeding was more profuse and irregular, and at times was entirely absent from the stool. Other ulcerative processes showed a much less tendency to hemorrhage, in cases of tuberculous enteritis blood was never found in the stools. In typhoid it was possible, however, to detect slight bleeding by the tests before any gross evidences were present, and such a means of diagnosing premonitory hemorrhages may be of value. The tests were entirely negative in all the ordinary gastric catarrhs, in gastroptoses, and in all processes immediately surrounding the intestinal tract, appendicitis, subphrenic abscess, etc. Where there was marked venous congestion present, as in cardiac disease with disturbances of compensation, blood could be repeatedly demonstrated in the stools, which disappeared as soon as the congestion was relieved. In catarrhal jaundice, the tests were positive, but in cases of cholelithiasis, they were always negative. The presence of blood could always be demonstrated in cases of secondary carcinoma of the liver. Although these tests have undoubted clinical value, their diagnostic value is not so evident on account of the large number of diseases in which intestinal hemorrhages can be demonstrated. The knowledge gained may be of value, however, in tracing the progress of a disease, such as gastric ulcer, and also in this manner judging the effect of the various schemes of treatment. To avoid the possibility of error, the author recommends that both tests be employed, one being a control on the other. Other factors to be borne in mind as invalidating the final results, are the possibility of an admixture of menstrual blood or that derived from hemorrhoids, bleeding gums or nose, and swallowed blood-stained sputum. In addition the tests have resulted positive when the patient had eaten food containing blood, such as raw meat.

Hematuria in Barlow's Disease.—Attention is called to the fact that à hematuria may be the only evident symptom of scurvy, by E. Neter (*Deutsche med. Woch.*, May 5, 1904). He reports a typical case in an eight-months-old infant, well developed, and fed during the previous four months exclusively with malted foods. The child did not seem quite well, but nothing was found on examination except the presence of blood in the urine. The diagnosis of scurvy was made by exclusion, and within eight days after changing the food to raw milk, the child was cured and no further blood could be detected in the urine. When hematuria appears during the end of the first year or later, and any affection of the bladder or the kidney can be excluded, the presence of scurvy should always be suspected. In doubtful cases, antiscorbutic treatment will soon afford a definite conclusion.

Effects of Facial Anomalies.—In addition to the known anomalies in different parts of the body which may exhibit a tendency to be far reaching in their effects, V. Babes (*Berl. klin. Woch.*, May 2, 1904) describes a class of cases where a primary, deep-seated anomaly of the face, and especially of the base of the skull, may lead to marked changes in the four extremities. He has had an opportunity of observing a series of such cases where the cranial anomalies were principally marked by early ossification and sclerosis of the base of the skull. The changes in the extremities usually affect all four, although the upper ones are often most marked. They may be manifested in three ways, (1) by the absence of a toe or a finger, or as general shortening of the limb; (2) by an increase in the number of fingers or toes, or a general increase in the size of the limbs; (3) by a change which includes a partial excess and defect, such as an increase in the number of metatarsal bones, with amalgamation of either fingers or toes, and increase or decrease in the length of the extremities. A remarkable fact about these phenomena is the symmetrical arrangement of these deformities as well as their resemblance to certain animal groups, the arthrodactylates, perissodactylates or the bidactylates. He details a number of cases to illustrate these observations and believes that there is a region of the skull which stands in close relation to the development of the extremities. In other words, that a center must be assumed to be in this region which determines the normal development of the extremities and any change in shape or character of the former will have as result an abnormal growth of the limbs. A further knowledge of this process may aid in clearing up some of the mysterious factors which underlie the differentiation of the various races and classes of animals.

A Rare Human Parasite.—Some three and a half years ago it was reported that a parasite found in cats and dogs in several countries of Europe and also in Siberia, had in two instances occurred in the human body. This parasite is the *Distomum felineum*. M. Askanazy (*Deutsche med. Woch.*, May 5, 1904) who first reported the disease in man has now made some further studies on its pathology. One of the cases in question had been diagnosed as tumor of the liver together with occlusion of the inferior cava. At autopsy there was found an extensive carcinoma of the liver, with numerous distoma and their eggs in the biliary passages. The same were also found in another man who had an ischias. The author has studied the possible relation of the parasite to the occurrence of the carcinoma in these cases and also the paths of infection. On investigating the stools of a number of patients suffering from the presence of tapeworm, for this parasite had also been found in the other two cases, the *Distomum felineum* was present in five. All these patients lived in a sea-port city. The fact that carcinoma of the biliary passages was also determined in a number of other cases, where the parasite was at the same time present, leads the author to believe that the epithelial proliferation due to their presence may possibly form a predisposing cause for the production of the cancer. Efforts to find the source of the infection resulted in the discovery that cats and dogs fed with raw fish, mainly the roach (*Leuciscus rutilus*), became infected with the parasite. This evidently accounts for the rather extensive distribution of the parasite in cats in sea-port towns. It is finally to be noted that one of the patients stated that he had been accustomed to eating raw fish.

Further experiments are now in progress in order to determine whether it is possible to produce cancerous growths in dogs by feeding them the infected fish. The intermediate form of the parasite has not yet been demonstrated and the complete cycle of development has therefore not been fully worked out.

Action of Formalin upon Urine.—Since formalin is being used more and more to preserve urine, it is interesting to study its action upon the chief chemical ingredients. C. STRZYZOWSKI (*Therap. Monatshefte,* May, 1904) reports as follows: Urea combines with formalin, forming a leucin-like sediment. This reaction may be used as test for urea; it is hastened by the addition of hydrochloric acid. Uric acid also combines, so that if precipitated, it will redissolve. Creatin and creatinin are not altered and the usual reactions are not interfered with. The same holds true for urobilin. With indican, however, 0.2 per cent. of formalin will render the ordinary reactions faint, and with one per cent. it will be absent altogether. The behavior toward albumin varies; sometimes traces are no longer precipitated on boiling preserved urine. The influence upon sugar, pentose, glycuronic acid, acetone, diacetic acid and oxybutyric acid is very slight, while bile-principles may be precipitated with the urea, from which they can be dissolved out by means of acid alcohol. Pettenkoffer's reaction is no longer possible in the presence of formalin. Summing up his observations, the author concludes that formalin is not suited for preserving urine, since it interferes with many important reactions.

Hemoglobin in Chronic Heart Disease.—Most cases of chronic endocarditis suffer from anemia and iron can often be taken for months without improvement. A. SCHOTT (*Münch. med. Woch.,* May 10, 1904) has often been surprised by the change of appearance of patients at Nauheim. A series of hemoglobin estimations show that with the customary physical and dietetic measures the blood improves markedly even where iron is withheld. As the figures approach normal, the symptoms disappear and the color returns.

Hemoglobin Estimation of Blood.—In contrasting the hemoglobin estimation of the blood with the Fleische apparatus with the actual determination of iron with the ferrometer, J. MITULESCU (*Zeitsch. f. klin. Med.,* Vol. 52, Nos. 3 and 4) finds that both figures agree very accurately unless the color of the blood is changed as in icterus or leucemia, or the blood is considerably altered so that the serum contains a considerable amount of iron owing to disintegration of red cells. In the latter class of cases, the percentage of iron of hemoglobin are not identical and both estimations are necessary.

Quantitative Determination of Pepsin.—J. A. GROBER (*Arch. f. exp. Path. u. Pharmak.,* Vol. 51, Nos. 2 and 3) has previously discovered that the pepsin normally present in every urine can be easily removed by digesting the urine with flakes of fibrin. The pepsin adheres very firmly to the latter and can only be washed off by dilute solutions of hydrochloric acid. It is probable that pepsin in the presence of acid forms a definite chemical compound with the latter for the critical temperature, that is, the temperature at which pepsin ceases to digest albumin is higher than with pure pepsin. A solution of acid, standardized against alkali with Congo-red, will possess a higher titre than the same solution in the presence of pepsin since pepsin shares the property of all proteids of neutralizing acid. In order to determine the amount of pepsin in a solution, a simple titration with standard acid solution will be sufficient.

Myxedema.—All cases of adult myxedema observed by A. MAGNUS-LEVY (*Zeitsch. f. klin. Med.,* Vol. 52, Nos. 3 and 4) came from regions where goiter is not endemic and some previous infection, such as erysipelas or influenza seemed to be the cause, or at least to stimulate the latent process. Tuberculosis certainly plays a minor rôle, if any at all. The most intense swelling affects head and face, and the rest of the body may be free except that the skin is usually dry and cold. In some the thyroid is enlarged and hard, in others it is absent altogether. Other common symptoms are cardiac changes, loss of sexual function, tremor, hippopotamus-like gait, loss of memory, apathy and depression. Complete idiocy is infrequent and very severe cases may present normal intelligence. Most cases were cured or very much benefited by thyroid medication. Sporadic cretinism also occurs in regions free from goiter and the disease generally dates back to the first years of life. The etiology is equally obscure; the symptoms correspond with those of adult myxedema, and treatment is generally successful. Endemic cretinism is more refractory toward treatment only if the diseased habitus has been transmitted through several generations. The first favorable symptoms which manifest themselves when thyroid is given, are a moderate perspiration and a sensation of warmth over the body soon followed by disappearance of constipation and changed voice. Equally good results were obtained with tablets, thyreoglobulin and iodothyrin, but thyreoantitoxin, iodide of potash and hypophysis tablets had no effect. It is often advisable to combine the treatment with baths, quinine, iron, arsenic and milk with vegetable diet. A large number of experiments conducted upon the patients showed that the respiratory exchange of gases is very much reduced owing to the diminished vital energy of the tissues, but it improves steadily with thyroid medication.

HISTOLOGY, PATHOLOGY AND BACTERIOLOGY.

Multiple Arterial Thrombi.—Sometimes occlusion of large vessels and sudden death occur in patients suffering from a lesion of the mitral valve and a diagnosis of embolism is generally made. H. EICHHORST (*Deutsch. Arch. f. klin. Med.,* Vol. 80, Nos. 1 and 2) is, however, inclined to view the process as thrombotic in nature, since the large masses found on the vessels are often altogether out of proportion to the small, delicate excrescences upon the diseased valves. Even if thrombi are present in the left auricle, their smooth surface argues against the possibility of an embolism. In a case observed recently the abdominal aorta from 12 cm. above the bifurcation, together with the left and right femorals, the superior mesenteric, the left renal, splenic, right pulmonary, left inferior thyroid and left carotid were found filled with clot. The immediate cause of death was occlusion of the mesenteric artery, and though the patient died half an hour after the accident and autopsy was performed only four hours after death, the intestines were already the seat of a hemorrhagic infarction and a peritonitis was beginning to develop. To decide the question of thrombosis or embolism, the walls of the affected vessels were examined microscopically. An intense inflammation was discovered here, probably set up by bacteria entering the vasa vasorum, incident to the recurring endocarditis. It is thus not difficult to understand that a thrombosis

may set in as suddenly and with the same symptoms as an embolism. The number of vessels occluded is frequently surprising and often the patients present but few symptoms.

Action of Fluorescing Substances on Toxins.—If diphtheria toxin is mixed with eosin or some other photodynamic dye, and then exposed to sunlight, many times the fatal amount may be injected with impunity. H. v. TAPPEINER and A. JODLBAUER (*Münch. med. Woch.*, April 26, 1904) injected diphtheria toxin into guinea-pigs after the animals had received a small dose of eosin or methylene blue for a few hours before. The site of injection was then exposed to the sunlight. The animals remained alive three times as many days as control animals after three to four times the fatal dose. The same holds true for tetanus toxin. The possibility of treating diphtheria and tetanus in man with these substances is seriously considered and snake poison would probably be influenced in the same way. There may be some advantage in choosing from the group such substances which have a special affinity for the tissues affected such as methylene blue in tetanus, where the nerve-tracts are principally involved.

Primary Endothelioma of Pleura.—One of the most interesting of tumors is the pleural endothelioma, since many questions concerning its origin and character are yet undecided. B. BONHEIM (*Münch. med. Woch.*, April 26, 1904) is of the opinion that the growth may start both from the lymphatic and pleural endothelium, since both classes of cells are of the same type and origin. Pathologically, two forms of tumor may be recognized: In one the pleura is uniformly thickened, so that the condition may be difficult to distinguish from callous pleuritis; in the other the pleura is studded with small nodules, suggestive of acuminated condylomata. The diagnosis is often difficult, but the following points are of importance: The exudate is generally upon the left side and serous in character at first. After every subsequent puncture, however, it becomes more hemorrhagic and finally has a dark chocolate color or suggests pure venous blood. Later punctures yield less and less blood and finally the heart will no longer return to its normal position. Very late in the course it may be necessary to puncture every few days. Microscopical examination of the fluid shows absence of tubercle bacilli and often groups of vacuolated tumor-cells. Despite the fact that the circumference of the thorax on the affected side is much increased, the ribs will approach each other, owing to pleural shrinkage. Other symptoms are gradually increasing scoliosis, severe pains and dyspnea. Frequently a resection of the ribs will considerably alleviate the patient's suffering, though it will hardly postpone the fatal issue.

Origin of Basophile Granules.—At present there is still considerable doubt as to the origin of basophile granules formed in red blood cells, some believing they are remnants of nuclei, while others believe them to be a peculiar form of degeneration. O. BOELLKE (*Virchow's Archiv*, Vol. 176, No. 1) has studied the blood in 43 cases of posthemorrhagic anemia and has found marked increase of polychromatophile erythrocytes with leucocytosis, but never megaloblasts or basophile granules. The same results were obtained after bleeding animals. Granules were also looked for in vain in embryos and in the newly-born, hence it is exceedingly improbable that they are derived from nuclei or stand in any relation to regeneration. Where the nemorrhage took place into the gastro-intestinal tract, an occasional punctate cell was found after some time, probably because the decomposition of bleed in the intestines led to the absorption of toxins. To prove that this can happen it is only necessary to administer some artificial blood-preparation, when the same granulations can usually be detected. There are especially common in pernicious anemia and there is every reason to believe that this disease depends upon an intestinal auto-intoxication, for the granules will disappear and the patients improve visibly if stomach and intestines are irrigated regularly, and if vegetable food, hydrochloric and citric acids are given. Another proof that stippling has nothing to do with disintegration of nuclei, is found in the behavior of blood toward pyronin and methyl green; all nuclei and their remnants will appear bluish-green, while the granules take on a bright red hue. It is also questionable if polychromatophilia has anything to do with karyolysis; probably it is merely a manifestation of protoplasmotic degeneration.

Nature of Symmetrical Disease of Lacrimal and Salivary Glands.—The microscopical examination of the glands of a case of symmetrical swelling excluded simple hypertrophy and led M. WALLENFANG (*Virchow's Archiv*, Vol. 176, No. 1) to group the conditions among pseudoleukemias. Why the toxins, which no doubt are the underlying cause, should select an isolated group of structures, could not be determined, but an affinity for certain tissues is a peculiarity which is noticed with many other poisons. The swellings are certainly not due to microorganisms, for no bacteria could be detected in the tissues with the usual stains.

Relation Between Acromegaly and Tumors of the Hypophysis.—In one case of pituitary tumor without signs of acromegaly examined by G. CAGNETTO (*Virchow's Archiv*, Vol. 176, No. 1), the tumor had destroyed the tuber cinereum and the corpora mammillaria and has penetrated into the lateral walls of the third ventricle. The tumor was a polymorphous telangiectatic sarcoma which had taken its origin from the anterior portion of the organ; its posterior portion was found compressed into a narrow strip of gland tissue along the floor of the sella turcica. In a second case, the typical skeletal and visceral changes were pronounced; the tumor, a hyperplastic struma with advanced adenocarcinomatous degeneration, had destroyed part of the sphenoid bone and had formed metastases along the spinal cord. The first case proves that the hypophysis may be the seat of a large tumor without acromegaly; the second argues in favor of the theory that acromegaly is a disturbance of metabolism which stimulates the bones of the skull and of the extremities to increased growth and sometimes the hypophysis to active hyperplasia.

Elastic Tissue in Tumors.—According to B. FISCHER (*Virchow's Archiv*, Vol. 176, No. 1) it is a mistake to believe that elastic tissue never participates in tumor formation. The great majority of benign and malignant growths contain but little elastin; in fact they show a decided tendency to destroy the fibers of the surrounding tissues by pressure and disintegration. Yet in others there is so much that the name "elastoma" would not be inappropriate. Among these are cavernous growths of the skin, certain cancers of the breast, endotheliomata of the dura, many fibroids and sarcomata. Occasionally the elastic tissue is not present in the form of fibers but as granules. Mixed tumors of the parotid and testes also give the reaction frequently. Often it is difficult to distinguish mucin and cartilage from elastin but Weigert's stain, if followed by prolonged differentiation in absolute alcohol, is specific.

PEDIATRICS.

Scurvy from Humanized Milk.—Municipal milk depots unquestionably do a great deal of good, but with the approach of summer, attention should be called to the fact that not only American observers in considerable numbers but those of Europe as well have recently

begun to recognize that there is an element not strictly human in the unlimited production and too free distribution of this so-called humanized food. Henry Ashby (*Brit. Med. Jour.*, Feb. 27, 1904) states that conditions which may well be called parascorbutic, but which are not sufficiently advanced to give the actual bone degenerations seen in scurvy, are apparent on careful observation in all children's hospitals where this form of feeding is employed in a proportion of about 6 to 1. There is anemia, anorexia, diarrhea, hematuria and sometimes a zone of pinkness at the roots of the finger nails. It costs the municipality a good deal of money to produce this humanized milk, because the rates at which the artisan class can afford to pay for it in England at any rate, does not begin to cover its cost. It is, therefore, of very great importance to know whether or not this well-meant effort is producing men and women of bone and brawn.

Lymphosarcoma of the Mesenteric Glands in a Three-year-old Girl.—This was the case of a child who was brought to the hospital with an enlarged abdomen which on palpation proved to be the seat of a soft swelling located in the right pelvis. Kovolkoff (*Roussky Vrach*, No. 10, 1904) elicited a history of trauma to the right side of the abdomen which was followed by hardening at the site of same. The child was rather pale, although fairly well nourished, with an occasional hectic flush due to variations of temperature. The circumference of the abdomen was 61 cm., and this kept on increasing until it reached 68.5 cm. in ten days; during this time the child's weight also increased five pounds. The heart as well as the lungs, though normal, were pushed upward so that the upper border of cardiac dulness was elicited at the third rib, and the lower border of the lungs was pushed up one rib higher. Every movement was accompanied by considerable dypsnea; respirations between 26 and 40 per minute; pulse 120. In view of the rapid growth of the tumor an abdominal section was performed and a bleeding tumor was found which was attached to the peritoneum. As it was impossible to extirpate the growth the abdominal wound was closed, and the patient was left to her fate. Her condition grew steadily worse, the body-weight kept increasing, although it fell soon before the fatal issue. There was severe dyspnea, edema of the extremities and stupor. On autopsy the tumor was found microscopically to be a lymphosarcoma, consisting of the same small cells as lymphatic tissue; the matrix of the growth could not be distinctly made out because of the great number of the cellular elements.

Postdiphtheritic Paralysis.—Notwithstanding the value of the diphtheritic antitoxin the various complications and consequences attendant upon the disease have not been greatly diminished by the use of it. The postdiphtheritic paralyses do not at all depend on the severity of the disease and are to be seen in grave as well as in comparatively light cases. N. F. Dourbrovsky (*Prakt. Vrach*, No. 9, 1904) describes two cases in boys ten and three years old respectively, in one of whom he found a typical paralysis of accommodation in both eyes as well as paralysis of the soft palate. This boy was treated with antitoxin (diphtheria) one and a half months before; the younger child suffered from strabismus and poor sight of the right eye. The older boy had a very severe attack of diphtheria. The pupils did not respond to light, the right is somewhat larger than the left; there is also some nystagmus in the right eye. There are no signs of anesthesia or paresthesia; the facial nerve is intact. The nasal voice and the ejection of food through the nose pointed to paralysis of the palate. According to the parents the disease was not accompanied by edema or any other symptoms that would point to premia. The strabismus appeared in the younger child suddenly, over night, accompanied by pain in the eye. It is so strongly convergent that the eye is turned entirely toward the nose. As regards treatment, the older boy was prohibited all school work and directed to wear dark glasses in view of the pronounced photophobia; both children were given strengthening diet, and the older boy Fowler's solution. Both children got well in about five weeks.

Bladder Irritation of Girls.—Little girls are more liable to urinary incontinence than boys. Every one is called upon to treat these little patients, and the condition is sometimes a difficult one to compass. If the urine contains blood and mucus, the following conditions naturally suggest themselves: Diabetes, azoturia, calculus, tubercle or malignant growth. The last are rare and improbable. W. D. Spanton (*Med. Press*, Feb. 24, 1904) states that he has found that a form of woolen undergarment, frequently used in England, has often been the cause of incontinence in little girls. The woolen hairs in this rather loosely woven tunic, if the garment fits the body closely, rub off easily and lodge on the labia. These woolen hairs are fitted with minute hooks which enable them to pass upward through the urethra into the bladder. Several children which he has examined and successfully treated have presented just this condition.

EYE, EAR, NOSE AND THROAT.

Treatment of Ozena.—It has been suggested by several observers that some etiological relation existed between this disease and abnormal width of the nares, and the proposition was therefore made to influence the course of the process by diminishing the size of the opening. This may be accomplished by the injection of paraffin into the inferior turbinate bone and H. Fliess (*Berl. klin. Woch.*, March 17, 1904) has employed the method in 12 cases. The nose is carefully cleaned and all crusts removed. The site of operation is then thoroughly cocainized and the paraffin injected into the most atrophied part of the turbinate and if necessary into the septum. Both sides may thus be treated at one or more sittings. All the cases showed distinct improvement, the relief from symptoms being very marked, although in no instance did a complete cure result. The only unpleasant sequelæ were pains in the frontal region in a few cases, which disappeared, however, in the course of a day. Hard paraffin, with a melting point of 50 to 52° C., is recommended as being most suitable and safest.

Choroidal Inflammation Due to Excessive Use.—Although continuous use of the eyes on small objects is frequently mentioned as a cause of inflammatory action, such cases are seldom seen in previously normal eyes and especially only after very prolonged use. D. B. St. J. Roosa (*Med. Rec.*, Feb. 20, 1904) reports the case of a physician who, after reading almost continuously for about ten hours, found that there was a blur over his eyes, apparently both being affected at first, but later he concluded only the right was involved. He took no pains to rest the eye and the condition remained about the same for six weeks, when he consulted the author, and it was found that the vision in the right eye was $^{20}/_{30}$ and the vitreous lumen was hazy. The left eye was normal. The case was seen several times during the subsequent five or six years and the vision in the right eye remained just the same. The haziness of the lumen cleared up and several spots of choroidal atrophy were to be seen. The retina was not at all involved and the process evidently did not progress. It is interesting to note that this is a traumatism instead of an infection of the eye and that such mechanical causes may appar-

ently produce conditions entirely similar to those from pure infection.

Celluloid Plate in Saddle-Nose.—Although the results obtained by paraffin injections have been, on the whole, satisfactory in rectifying deformities of the nose they are not entirely void of danger, for several cases of embolism have followed the use of this material. J. Wiener, Jr. (*Med. Rec.*, April 16, 1904) successfully introduced a celluloid plate some three years ago in a case of marked deformity with subsequent most happy results. He made an incision about one-quarter of an inch long on the under side of the nose and through this small incision with iridectomy scissors, a subcutaneous flap was made over the depressed bridge of the nose. A piece of celluloid plate about half an inch wide, an inch long and a thirtieth of an inch thick, was sterilized by boiling for a few minutes in soda solution, readily molded to the shape of the bridge of the nose, and then introduced through the small opening until it occupied the space of the subcutaneous flap. One suture closed the wound, and to avoid pressure no dressing was applied. Only slight swelling occurred, and no subsequent discomfort has appeared from the presence of the plate. The profile of the face is very satisfactory.

GENITO-URINARY AND SKIN DISEASES.

Mercurial Exanthemata.—The most common form of mercurial eruption, according to E. Tomasczewski (*Zeitsch. f. klin. Med.*, Vol. 51, Nos. 5 and 6) is mercurial acne, such as occurs on the hairy parts of the extremities in the form of nodular infiltrations of livid color, about a hair follicle. This, as well as various forms of transient dermatitis on the flexor surfaces of joints are only induced by the external application of the drug. Eruptions after internal use may be of manifold character, from an erythema without desquamation or subjective symptoms up to severe vesiculation and pustulation with involvement of nails, hair and the mucous membranes and such severe constitutional disturbance that a general disease may be suspected. Thus measles, scarlet fever, erysipelas, hemorrhagic purpura, multiform exudative erythema and acute eczema may be simulated. Even the diazo-reaction may be positive. The appearance of an eruption is independent of the combination employed and of the way it is employed. There is nothing typical about form-grouping and distribution of the lesions but the peculiar violet color, extensive desquamation and the rapid disappearance after the drug is stopped, are often typical. If the drug is introduced anew, the diagnosis can often be made by observing an exacerbation. In some cases mercury can be detected in the urine and the feces. Idiosyncrasy plays an important rôle, but it is more an idiosyncrasy of organs than individuals, for in some the skin is readily affected, in others the internal organs, in still others the nervous system. Patients who react readily by salivation and rise of temperature must be classed among the latter. Strangely enough, the organs in which mercury is usually deposited, are not the same as those affected by idiosyncrasy. The same organ will generally continue to react even where the method of application is changed. In conclusion, a peculiar local reaction in syphilis is mentioned which may be of diagnostic value. Twelve to twenty-four hours after an injection of salicylate of mercury a macular or maculo-papular luetic eruption will spread or become confluent and the color will become more violet, so that the experienced can suspect that an injection was given, if he has seen the case before.

Etiology of Alopecia Areata.—Since the publication of Sabouraud's work on seborrhea oleosa and its bacteriology, a great impulse has been given to the trophoneurotic theory of its origin. The old belief, of course, was that it was invariably of a parasitic nature. Arthur Whitfield (*Lancet*, March 5, 1904) states that although Sabouraud was forced to give up his belief that seborrhea was the cause in all cases and to differentiate a special variety in children, stated to be due to some cause other than invasion of the microbacillus of seborrhea. Recently Jacquet has directed attention to the abnormalities in the dentition of these children, which he supposes to have produced a sufficient increase of nervous irritability to account for the bald spots. Although but little work has been done on this subject to prove or disprove the contentions of this last observer, the author believes that it is probable that nerve irritations, particularly of sight, may in certain cases be responsible for the disease. Headache and localized neuralgia, as is well known, have often been accompanied by alopecia areata. He cites four cases in which he found the vision defective, in each of which persistent local treatment was without avail. All four cases were promptly cured by the use of suitable glasses.

THERAPEUTICS.

Red Light Treatment of Smallpox.—If it be questionable whether or not we have as yet isolated the sporozoon of this disease, there is no doubt that advances have been made in the manner of its treatment. J. T. C. Nash (*Lancet*, March 5, 1904) records 12 cases treated in ordinary light and 13 treated under red light. In the first table, there were four deaths. In the second table there was but one. Medical treatment was practically confined to acetozone, about six grains a day. The author believes that the suppurated stage was considerably modified by the influence of the red rays or by the exclusion of the other light elements. The one death recorded was from confluent hemorrhagic smallpox, the case being moribund on admission to the hospital. One disadvantage of a red light ward is that the physical appearance of the smallpox eruption cannot be appreciated or demonstrated as is possible in ordinary daylight.

Treatment of Eclampsia.—The employment in eclampsia of chloral hydrate in suppositories is an old and well-tried remedy, and Mansuroff (*Prakt. Vrach*, No. 11, 1904) reports a case where this drug has undoubtedly saved the life of a twenty-year-old primipara that is of sufficient impressiveness to be abstracted here. The woman when brought to the hospital had a series of extremely severe eclamptic attacks that seriously threatened her life. She was at once given an enema, and then after an evacuation of the bowels, a glass of warm water was injected containing 15 gr. of chloral hydrate and 10 drops of the tincture of opium. As this was not retained for any length of time, another one was administered; cold to the head and mustard on the neck. The condition of the patient precluded the possibility of any internal administration of drugs. In 3½ hours a third clyster was administered; by this time the convulsions ceased though the patient was still unconscious. Eight hours later the patient opened her eyes and complained of vomiting. A fourth clysma was given which induced quiet sleep for an entire day. Later on uterine contractions supervened, and the patient gave birth to a live, strong baby. There was an alarming post-partum hemorrhage, after which the patient felt considerably relieved, "much clearer in her mind." Post-partum course normal. Altogether there were nine attacks, of which four were of great severity, lasting over five minutes each and followed by unconsciousness of many hours. It is hard to undestand why sciousness of many hours. It is hard to understand why as possible, by either version or forceps.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the MEDICAL NEWS will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate, the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

RACIAL DEGENERACY AND AMERICAN PROGRESS.

LONG before the days when Horace described the old man as *laudator temporis acti se pueri*, a praiser of times past when he was a boy, it was the custom for the elders of each successive generation to insist that things are not what they used to be, and that while the end may not exactly be in sight, at least it is being approached with giant strides now that they are no longer young. The world has not changed much and every generation since Horace's time has had many who have felt this way.

In our day everybody dabbles in medicine and as a consequence medical terms are used to express pessimistic ideas, and racial degeneracy and the like are heard on every side as one of the easily recognized signs of the times. We are not of marked pessimistic tendencies ourselves, and so we are glad to note that at least one of the important magazines, *The World's Work*, is ready to lend its columns to a disproof of the idea that our generation is degenerate, and to show on the contrary that there is noteworthy proof of progress in every department of life.

Of course this will not suit the pessimistically inclined. There are many followers of Schopenhauer, of whom some one recently said that he was never so happy as when he was realizing how miserable he was. It would be well, however, for some of the croakers to consider seriously how ample an apology can be made for our present conditions, for the series of articles mentioned seems to make out a very good case for the theory that conditions in American life are growing better every year. Our schools are better, our educational system is constantly developing, and our great universities are coming to be examples to the world in their line. In spite of the frequent assertion of the lack of esthetic sense among Americans, the appreciation for art is widening every year, and the liberal patronage of art is becoming the fad of every American who has any money.

Notwithstanding alarmist reports in sensational newspapers there is less dishonesty and those who are engaged in questionable financial operations are being pilloried in public in a way that shows a higher sense among the people of morality in contradistinction to mere legality that is very promising for the future. Charity organization has done its work; our tenement houses have been improved so that now life has become much more livable in the slums and health is much easier to maintain. If we consider the difference in the conditions that obtain at the present moment in New York's most thickly populous district, bad as they may still be, and admitted to be in many ways still capable of improvement, they are so far above those which were common even a quarter of a century ago as to make the comparison seem indeed odious. Even municipal beauty, for its own sake and for its uplifting effect upon even the lower classes, has become an object in the civic life of great cities and all the citizens are sharing in the inspiring effect of the application of art principles even to our city streets and vistas.

Long ago Edward Everett Hale said "Look up, not down; look in, not out, and lend a hand." At the present moment there is much reason to be proud of what has been accomplished in recent years by those who have not idly talked race degeneracy, but who have shown ways and means and possibilities of improvement. The present generation is not a bit worse than any of its predecessors and is in many respects decidedly better. There still remains much to be done for general improvement, much that will redound to the health as well as the happiness of mankind, much in which members of the medical profession must be, as they have been in the past, leaders. Nothing is so inspiring as to find how much good has

been accomplished by what has been done already. Hence we welcome as especially opportune this successful attempt of our New York contemporary to demonstrate by actual statements of fact that the talk of degeneracy is idle and empty complaining, while the world's willing workers are accomplishing great things.

MEDICAL GRAFT.

The Physicians' Club of Chicago recently devoted a whole evening to the discussion of professional graft, without arriving at a satisfactory definition of the word; but Dr. Enricus Cordus, who published a very keen and clever little paper on "Medical Graft" in the June number of *The World To-Day*, defines graft,—political, medical, legal, etc.,—as "unearned pay obtained for real or fancied service." He then outlines some of the opportunities offered to physicians to obtain money from an ignorant public.

The temptation to perform unnecessary operations, and to make superfluous visits, is often offered by the patient's own anxiety and credulity, and it is small wonder if some of the younger men yield to the easy method of increasing their income and become repeaters and alarmists. The size of the fee has no relation to graft. A wealthy man is quite as willing to pay a large round sum for expert care in saving his life, as he is for the legal advice that saves his property, but the physician who demands cash payment of a sum that is out of all proportion to his patient's means, before he will come to look at the case, is a grafter of the meanest order, whom his brothers send to Coventry along with those who extort hush money, and threaten blackmail to the indiscreet patients who have been in their care.

But as a rule, Dr. Cordus says, he finds that out and out grafting is left to quacks. Personally, he says he has known during thirty years, only three medical men to whom he could honestly apply the word grafter. One of them left the profession and became a gambler; the second committed suicide while in jail, and the third, who ought to be serving a life sentence in a penitentiary, occupied a position on the staff of a temperance hospital.

There is a distinct tendency toward commercial graft that is fostered not by the physician himself, but by the promoters of mineral waters, commission-giving drug stores, or proprietary firms, who offer the physician stock, or a percentage for the sake of his exclusive patronage; but few such cases ever amount to anything, and as the initiative always comes from the outside, it is hardly fair to blame the physician if he occasionally falls prey to the promoter.

Dr. Cordus discusses the question of so-called hospital graft, with the very just conclusion, that it is the public that is the grafter. "No other profession," he says, "is as absurdly altruistic as physicians, in this matter of hospitals. They give their time and services to institutions that could not possibly exist without them, but have no voice in their management, and if by any chance their attitude becomes business-like instead of charitable, it is hinted that their motives are mercenary and unethical. There must be on this matter as well as in the matter of dispensary practice a radical change within a few years, or the grafting public will hold the ethics of the profession in derision."

The conclusion of the article places the medical profession justly, we feel, among the most honorable of all professions. Oliver Wendell Holmes, when asked why physicians did such things as have been suggested, replied that he never knew one to do so. "Once," he said, "I looked up such a report, and found that the man was a quack. Physicians never do such things."

"In the face of limited income, perpetual demand for charity, and innumerable opportunities for graft, the American physician is, as a rule, the graftee, and not the grafter."

ECHOES AND NEWS.

NEW YORK.

Appointment of Dr. Pryor.—Dr. William R. Pryor Professor of Gynecology at the New York Polyclinic Hospital, has been appointed Attending Gynecologist to St. Vincent's Hospital.

The P. & S. and Hospital Appointments.—The pre-eminent position of the P. & S. in the matter of hospital appointments is made prominent in this last year's success. Of the graduating class of 174 of 1904, 131 men had obtained hospitals by July 1, 1904.

Hospital for Queens Beaches.—A movement is under way for the establishment of an emergency hospital in the Fifth Ward of Queens Borough, which comprises the summer resorts of Far Rockaway, Edgemere, Arverne, Belle Harbor, and Rockaway Beach. A permanent organization has been organized to push the project toward a reality.

St. Elizabeth's Hospital.—The new St. Elizabeth's Hospital will be completed in September. The new building is situated on the north side of Fifty-first Street between Ninth and Tenth Avenues. It consists of five stories and basement, and will be divided into thirty-five private rooms and two wards, these having from fifteen to twenty beds each. The hospital admits women and children. The old building is still situated on Thirty-second Street, on the site of the new Pennsylvania station, it being the only structure left.

This Year's Charitable Appropriations in New York.—"The amount of appropriations made this year for new buildings, repairs and improvements at the New York State charitable institutions is somewhat

disappointing," writes *Charities*. "The appropriation bills, as passed by the legislature, made a fairly satisfactory provision for the wards of the State, but before these bills became law the appropriations which they carried were reduced over 30 per cent. by the Governor's veto of some fifteen of their items. The figures are given for brevity and for convenience of reference in the following table:

	Amount of Items Provided for in Appropriation Bills.	Amount of Items Vetoed by Governor.	Amount of Items Approved by Governor.
State Industrial School, Rochester	$185,000	.....	$185,000
House of Refuge for Women, Hudson	9,900	$7,500	2,400
Western House of Refuge, Albion	17,000	12,000	5,000
New York State Reformatory for Women, Bedford	59,750	43,000	16,750
Society for the Reformation of Juvenile Delinquents in the City of New York	4,000	.....	4,000
Syracuse State Institution for Feeble-minded Children	4,500	.....	4,500
State Custodial Asylum for Feeble-minded Women, Newark	46,600	41,000	5,600
Rome State Custodial Asylum	96,150	42,500	53,650
Craig Colony, Sonyea	42,250	28,950	13,300
New York State Soldiers and Sailors' Home, Bath	28,090	.....	28,090
New York State Woman's Relief Corps Home, Oxford	5,150	3,000	2,150
Thomas Asylum for Orphan and Destitute Indian Children, Iroquois	16,000	.....	16,100
New York State School for the Blind, Batavia	34,930	1,500	33,430
New York State Hospital for the Care of Crippled and Deformed Children, Tarrytown	.....	.....	.....
New York State Hospital for the Treatment of Incipient Pulmonary Tuberculosis, Raybrook	7,350	.....	7,350
	$556,770	$170,450	$377,320

The largest of the items vetoed was $40,000 for an employees' cottage to accommodate 100 at Rome, $38,000 for two cottages for inmates at Bedford, $28,000 for a cottage for inmates at Newark, and $22,950 for the enlargement of the central heating and power plant at Craig Colony. It is estimated by the fiscal supervisor of State Charities that the last named improvement would save the State from $4,000 to $5,000 a year, and in the interests of the taxpayers it seems unfortunate that such an appropriation should be deferred. The veto of the appropriations for new buildings for inmates, or for employees, who would vacate space in residence buildings which could be used for inmates, at the institution for defectives, are particularly to be regretted, as there are large numbers of defectives now unsuitably cared for in almshouses and homes. The Reformatory for Women at Bedford has already passed the limit of comfortable capacity and is equally in need of expansion, especially in view of the fact that a new law adds eleven new counties to the district from which it draws its inmates. The Governor's reason for vetoing most of the items, this year as last year, seems to be that in his opinion the necessity for them is not immediate. Delay in making necessary repairs and providing necessary buildings seldom results in a saving to the State, however, for repairs neglected cost more in the long run, and the postponement of needed new accommodations subjects the institutions to inconvenience and leaves society without the protection which it ought to have against the increase of the defective and the delinquent classes. Most of the appropriations which are made this year were asked for last year and refused, and it is probable that the appropriations which have been refused this year will have to be allowed next year. The amount of the items vetoed, therefore, does not represent a saving but a deferring of expenditure.

New York State Tuberculosis Hospital.—This State institution at Raybrook, N. Y., opened on July 1, with accommodations for about fifty patients. A camp of tents has accommodations for forty-four. To patients who can afford to pay for treatment, a charge is made of the actual cost of maintenance. Only patients with incipient tuberculosis are admitted. The examiners in this city are: Dr. Hermann M. Biggs, 5 West Fifty-eighth Street; Dr. Egbert Le Fevre, 52 West Fifty-sixth Street; Dr. George F. Laidlaw, 58 West Fifty-third Street, and Dr. W. H. Vandenburg, 32 West Forty-ninth Street. The institution may be reached by the New York Central or the Delaware & Hudson railroads. Dr. John H. Pryor, formerly of Buffalo, is superintendent of the hospital.

Plans for the New Manhattan Eye and Ear Hospital.—The Manhattan Eye, Ear, and Throat Hospital, now at Forty-first Street and Park Avenue, is soon to be moved. For many years the accommodations have been insufficient. In the thirty-four years of the hospital's existence the city has grown in population from 950,000 to about 4,000,000, and in area from about 20 square miles to over 300. This great increase has not been met by a proportionate growth on the part of the hospital. The increase in the number of patients from 1,717 in 1869 to 28,479 in 1903, gives an idea of the overtaxed condition. When it became absolutely necessary to meet the requirements for more room, a building committee was formed and ways and means were discussed to the end of acquiring a new site and building. The present property is worth over a half million dollars, and this, combined with the voluntary contributions and other revenues possessed by the institution, constituted a fund sufficient to warrant the acquisition of the nine lots next door to the Baron Hirsch Trades School in East Sixty-third Street. York & Sawyer were selected to design the new building. The capacity of the old building under normal conditions is fifty ward patients and eight private patients. The new institution will accommodate 400 ward patients and about 50 private patients. There will be two buildings; one on the north side in the shape of a horseshoe, so that its wings will be lighted on three sides and receive the sun all day, and the other a lower larger building on the south side for administrative purposes, including rooms for nurses, servants, the superintendent, and the members of the staff. In the north building or hospital proper the entrance floor is to be occupied by the reception rooms and offices, and the floor directly above will be the eye clinic. Above this floor there will be six more stories of wards. Above these will be two floors for private patients, and the next floor will contain the three separate operating rooms for the eye, ear and throat departments. On the top floor will be the pathological and bacteriological laboratories, the kitchen, the dining rooms for nurses, and other apartments considered necessary in a modern hospital. Each physician is allowed to send his poor patients to the institution, but he himself must prescribe for them and he alone is responsible for their welfare. These patients must pay for their treatment if their doctor thinks they can do so, thus preventing any abuse of the hospital privileges. The private patients occupy separate rooms, for which they pay; and they are taken care of by their own physician. No one is refused admittance except in rare cases when the patient can but will not pay the small fee charged. The hospital has a post-graduate department, where any physician in possession of a degree may take a course which lasts about three months, and in this way become thoroughly familiar with new

phases of surgery exemplified in the various departments comprised by the hospital.

Manhattan Dermatological Society.—Regular monthly meeting held on Friday evening, June 4, 1904, at the residence of Dr. R. Abrahams, with Dr. I. P. Oberndorfer presiding. The following cases were presented:

Dr. L. Weiss showed two cases; one a young girl with a sluggish granulating ulcer on right cheek; of several months' duration and exceedingly rebellious to treatment in the beginning, but later on doing well under creosote salicyl plaster; presented as a scrofuloderma. Case II. was one of erythema iris, in a young girl of fourteen years; lesions present on upper right and left arms, upper right and left thighs, and one on abdomen; the lesions were markedly symmetrical, diagnosis concurred in.

Dr. E. L. Cocks exhibited a boy with palmar psoriasis; the question of differentiating chronic eczema, or possibly syphilis, was answered by the presence of guttate typical psoriatic lesions on other parts of the body. Diagnosis accepted.

Dr. Gottheil showed a well-marked case of leucoderma in an elderly male patient; these patches were absolutely white and blanched, in marked contrast to the deeply pigmented areas of surrounding skin; the latter was so extensive and deeply pigmented as to raise the question whether a new deposit of pigment was coincidently going on with disappearing pigment in other areas. Dr. Gottheil inclined to accept this view. Dr. Gottheil also showed an elderly male with a large fungating, granulating mass on right wrist, which he termed fungating epithelioma; of many months' duration and slowly increasing.

Dr. I. P. Oberndorfer presented the patient who was shown at the May meeting; at that time Dr. Oberndorfer made a provisional diagnosis of morphea; the lesion on the chin showed marked induration. Dr. Oberndorfer reports that under K.I. treatment the condition is considerably improved.

Dr. Geyser showed two cases. The first was shown to illustrate the beneficial effects resulting from high frequency currents in the treatment of acne indurata of the face; this patient's condition improved wonderfully, so that no lesions are now apparent, and there being no recurrence within the last four months; patient was seen at a previous meeting.

The second patient, a girl of eleven years, after exposure, developed typical vesicles, blebs, redness and itching, characteristic of dermatitis venenata, on both hands, dorsal surface; eruption faded away in the fall; the following spring a somewhat similar outbreak occurred; this without exposure, to remain all summer and again fade away in the fall. A third outbreak occurred the following spring (this year). Some signs are now present, consisting of an eczematous condition. Drs. Cocks and Gottheil can recognize only an eczematous condition present; it may have been a dermatitis venenata originally, with recurrent attacks of diminishing severity; subsequent attacks not necessarily due to new exposure. Dr. Oberndorfer diagnosed recurrent dermatitis venenata; the second attack, unlike the first one, needed no direct exposure.

Dr. R. Abrahams presented a mother and her eleven-weeks-old infant, both subjects of syphilis; he believes the mother's acquired and the infant's hereditary; the mother shows squamous lesions on palms and soles, and some on shins. The mother states she noticed a swelling on labium and in the groins six weeks after her last confinement One week ago child's body showed a typical roseola. Husband states he had a chancre, but many years ago; no recent lesion. The question Dr. Abrahams asked, Did the child infect the mother? or was the mother long syphilitic? Dr. Ochs believes the child's syphilis is hereditary; the lesion on the mother's labium was probably a late secondary lesion; the mother having had syphilis for some time. Dr. Sobel expected to find lesions on the child (if congenital) much sooner than ten weeks after birth. Dr. Gottheil argues with Dr. Ochs; infection of the mother is probably of one or two years' duration. Dr. Oberndorfer said history was incompatible with congenital syphilis.

Dr. Abrahams then showed a woman aged thirty-five years; history of long standing bronchitis, headaches, general malarial and gradual weakness, and loss of flesh; patient is poorly nourished; the father died of diabetes and a brother of tuberculosis. Ten months ago the skin began to get dark, on exposed surfaces especially. A provisional diagnosis of Addison's disease was made. Dr. Gottheil did not coincide in this view; he believes the pigmentation due to continual exposure and on the body to the existence of a chronic eczema and continual scratching; the latter still quite evident. Dr. Sobel takes exception to diagnosis of Addison's disease; the mucous membranes are not involved; history of diabetes in the father and beginning symptoms of diabetes in the patient, such as throat, polyuria and loss of weight, make him think of the condition known as bronzed diabetes. Dr. Wainwright was of the same opinion; history was suspicious of diabetes. Dr. L. Weiss considers but two conditions: (1) pigmentation due to exposure; to long continued scratching on body and (2) patient's history favors diagnosis of bronzed diabetes. Dr. Oberndorfer was inclined to agree with Dr. Abrahams in calling it Addison's disease.

Dr. Abrahams also presented a case of dermatitis exfoliativa with alopecia capitis; the latter he considers a rare combination. Dr. Gottheil believes the two conditions to be distinct and have no connection.

Dr. B. F. Ochs presented the following cases: (1) A male; six years ago a row of hard papules showed on the face; they assumed a crescentic outline and the patches assumed the size of a silver dollar; the patches were symmetrical; one on each side of face near the lobe of the ear; never got well; the center of patch is hyperemic and the margins, consisting of hard papules, are distinctly raised and hard to the touch. Dr. Gottheil considered it lues. Dr. Cocks entertained leprosy. Dr. Oberndorfer said symmetrical grouping favored diagnosis of lues. (2) A male with gumma of the tongue; a hard, globular mass on dorsum of tongue; present about two weeks and is beginning to ulcerate. The scrotum shows old striation and patient states at this site he had a sore (chancre) four years ago, which was cauterized and which healed rapidly. (3) An interesting case of syphilis in husband and wife; the husband had his chancre six weeks ago on the penis, followed by inguinal adenitis and roseola; evidence still present; the wife shows axillary, epitrochlear and cervical adenitis, and a chancre on left tonsil; mode of infection not determined.

PHILADELPHIA.

Sentenced for Malpractice.—One of the results of the coroner's recent crusade against malpractitioners has been the conviction of Dr. G. A. Appel, of Germantown, who was sentenced by Judge Davis to two years in the penitentiary. Two other indictments against him were dropped.

Free Maternity Incident Closed.—The Free Maternity Hospital Service of Philadelphia which two years ago scattered some 15,000 contribution boxes throughout the State, has been ended by the acceptance of the receiver's report. The society was originally re-

fused a charter because its expenses were out of proportion to the work accomplished. The funds in the boxes will only cover the cost of litigation.

First Conviction of Illegal Practitioner.—The first conviction under the recent activity of the State Board of Medical Examiners is that of Thomas E. Eldridge, who has been fined $200 for practising medicine illegally. The maximum penalty is $500. Eldridge possessed a diploma given him by the Eastern College of Therapeutics and Psychologic Medicine of Philadelphia, but no such institution is recognized by the board. Eldridge employed electricity and the X-rays and also essayed the giving of drugs which proved his undoing.

Douglass Memorial Hospital.—Plans are being considered to provide new buildings and equipment for this institution, which is conducted for the benefit of the negroes of the city. The entire staff, except the consultants, are colored, and this year a class of five colored nurses was graduated. The work of the hospital has been steadily increasing during the eight years of its existence.

Food Adulteration Prosecutions.—Prosecutions by the State Dairy and Food Commissioner have reached practical results in holding for court 14 milk dealers whose products have been analyzed and found to be adulterated. Warrants for nearly 20 more have been issued. The Bureau of Public Health and Charities is co-operating with the State officials. Many dealers outside of Philadelphia are also involved in the investigation of Commissioner Warren, who is beginning to reap the results of his untiring efforts. In Altoona 30 grocers have been arrested for selling adulterated apple butter, chocolate, cherries, and maple syrup. Definite steps have been taken toward fitting up a chemical laboratory in connection with the Commissioner's office at Harrisburg.

CHICAGO.

Commencement Exercises of Dearborn Medical College.—This college graduated its first class June 30, at which time degrees were conferred on fifteen men and three women. The degrees were conferred by the President of the College, Dr. L. Blake Baldwin, and the Doctorate Address was delivered by Judge Richard S. Tuthill.

Chicago Hospital.—The Chicago Hospital Building Co. has given a deed of the property to the Chicago Hospital for a consideration of $135,000. The property is located 110 feet east of Cottage Grove Avenue, and has a frontage of 75 feet and a depth of 132 feet. The hospital is located at 452 Forty-ninth Street. The improvement consists of a five story brick building. The transfer was made subject to an incumbrance of $30,000, and the grantee has given a trust deed to the Merchants' Loan and Trust Company to secure an additional loan to John T. Binkley, of $40,000 for five years at 5 per cent.

Investigations of Health Commissioner Reynolds in Regard to Dairy Farms.—The following is a summary of the most important results of the Commissioner's personal investigation of a number of dairy farms in this and adjoining States from which Chicago receives its milk supply:

1. An increasing proportion of Chicago's milk is delivered to the consumer within twelve hours after milking. The bulk of it, however, is from twenty-four to thirty-six hours old before delivery. There is no insuperable reason why it should not all be delivered within the shorter period and every effort of the Department is being made to this end. 2. There is much room for improvement in the conditions of milk production on nearly all the dairy farms visited, except those under the direct supervision of a few large contracting firms. The dairy inspectors of the Department are engaged in visiting this class of farms, explaining to their owners the necessary requirements, reporting upon their conditions, and recommending the exclusion of their product from the Chicago market if, after a reasonable time, they fail to conform to these requirements. 3. It costs more to produce clean milk than dirty milk—therefore, cheap milk is, prima facie, impure and unwholesome milk and the housekeeper who buys it is helping to perpetuate unclean conditions of dairies and helping to swell the death rate of the city, by having her babies die off from diseases caused by poor and impure milk. The consumer should make it an object to the milk producer and the milk dealer to furnish a clean, fresh and wholesome product, by being willing to pay a fair price for such product and by giving personal attention to its quality and proper care after its receipt.

CANADA.

Annual Meeting, Ontario Medical Council.—The annual meeting of the Ontario Medical Council was held during all of last week in the Council Chambers, Toronto, under the Presidency of Dr. J. A. Robertson, of Stratford. Since last session two prominent members have died, viz., Dr. V. H. Moore, Brockville, and Dr. J. H. Sanster, Port Perry, their places having been filled by Dr. Herald, of Kingston, and Dr. Bascom, of Uxbridge. After hearing the annual presidential address, the following officers were elected for the ensuing year: President, Hon. Dr. Sullivan, Kingston; vice-president, Dr. A. A. Macdonald, Toronto; Registrar, Dr. P. A. Pyne, M.P.P.; Treasurer, Dr. H. Wilberforce Aikins; Auditor, Dr. J. C. Paton. A communication was submitted from the Hon. Alfred Lyttleton, Colonial Secretary, referring to the fact of a private member's bill before the British House of Commons, providing that when any part of a British possession was under both a central and a local legislature the King might by order-in-council declare any such part under a local legislature to be a separate British possession. The object of this measure was to enable reciprocal arrangements to be entered into under the Medical Act of 1886 with such provinces of Canada as desired to do so. The Ontario Council thought that Great Britain in this matter would be having the best of any such bargain, and in the absence of more explicit information on the subject laid it over until the next session in 1905. The Council decided to sell their present building and erect new quarters and tenders will be called for without delay. The matriculation standard was raised, 40 per cent. now being the minimum required on each subject and 50 the minimum on the aggregate in Ontario. A prolonged discussion took place on alcohol in patent medicines, and it was resolved to memorialize the Dominion Government on the matter requesting that every such article of manufacture exposed for sale should have the formula printed thereon. Another matter of great importance dealt with was the question of an authorized tariff for the Province. A special committee had had this matter under their attention during the past year with the result that their scheme submitted to Council was endorsed and recommendations made that the legislature be approached and same be legalized. The examination committee reported that at the examinations just held 142 candidates had presented themselves in the final year, of whom 93 passed and 49 failed to qualify. An amendment was adopted to the fifth-year course providing for these students receiving a certificate after having spent a year in a hospital with over fifty beds, or for one year assistant to a doctor, instead of taking the fifth year lectures.

Congress of French Doctors.—The second congress of French-speaking physicians of America was held in Montreal, June 28 to 30, the sessions being held in the Convocation Hall of Laval University. Dr. Pozzi was the official delegate representing the Academie de Medicine de Paris and while in Montreal performed operations in the Notre Dame and Royal Victoria Hospitals.

Appointment.—The provincial government of New Brunswick has appointed Dr. J. V. Anglin, of Montreal, superintendent of the New Brunswick Hospital for the Insane at a salary of $2,500 per annum. Drs. G. A. B. Addy and Travers have been looking after the patients at the hospitals since the resignation of Dr. Geo. Hetherington some months ago.

News Items.—Laval University, Montreal, this year conferred the M.D. degree upon 40 candidates, and 18 received the degree of Bachelor of Medicine.

Dr. R. J. Manion, gold medallist from Trinity University has been appointed to the house staff of the General Protestant Hospital, Ottawa.

Dr. R. Tait McKenzie, head of the practical anatomy department at McGill University has been invited to become medical superintendent of the college gymnasium of the University of Pennsylvania. Dr. McKenzie is at present in Paris, and it is understood that he may possibly accept.

At the coming meeting of the British Medical Association Dr. T. G. Roddick, M.P., of Montreal, and Dr. William Osler, of Baltimore, will have conferred on them by Oxford University the degree of Doctor of Laws, *honoris causa*.

A sanitarium for the treatment of consumptives is to be erected at Kamloops, B. C., and toward the purpose the Canadian Pacific Railway will contribute $5,000.

GENERAL.

Harvard Medical Graduates.—On June 29, the faculty of the Harvard Medical College conferred the degree of Doctor of Medicine upon 130 men.

Harvard's New Buildings.—It is announced, says *Science*, that work on the buildings for the Harvard Medical School has not progressed as rapidly as had been hoped, and that they will probably not be occupied until the autumn of 1906, instead of 1905, as was originally expected.

Yale Medical Graduates.—The *Times* says the graduating class of the Yale Medical School numbered twenty-three. The following were announced at the commencement exercises on June 29: Degree of M.D., *cum laude* to Emanuel Charles Fleischner, New Haven, Conn.; Carlos Grout Hillyard, Saxtons River, Vt.; Julius Harold Rush, Washington, D. C.; Nathan Tolles Pratt, Bridgeport, Conn., and Burton Isaac Tolles, Ansonia, Conn. The Campbell Gold Medal was awarded to Emanuel C. Fleischman with honorable mention to Nathan T. Pratt and the Keese prize of $145 was divided equally between Charles G. Hillyard and Nathan T. Pratt, with honorable mention to Julius H. Hurst.

Warren Prize.—The Warren Triennial Prize of the value of $500, in the gift of the Massachusetts General Hospital, has been awarded to Dr. Max Borst, extraordinary professor of pathological anatomy in the University of Würzburg, for a dissertation entitled "Neue Experimente zur Frage der Regenerationsfähigkeit des Gehirns."

Statue to Dr. William Elias B. Davis.—We learn from the *Alabama Medical Journal* that the memory of Dr. William E. B. Davis, late of Birmingham, Ala., will be appropriately perpetuated by the erection of a monument by the Southern Surgical Gynecological Association, of which Dr. Davis was the originator as well as founder. He not only conceived the idea, but organized the association in all its details and served as its secretary and executive officer for thirteen years. The association does well in thus testifying its appreciation of this distinguished physician, whose memory will live in spite of granite or bronze. The statue will be made by G. Moretti, who was the designer of Vulcan (the Colussus iron man which represents the Birmingham district at the St. Louis Exposition) and will be in bronze, 7½ feet high, standing upon a granite pedestal 9½ feet high. Signor Moretti is now making a marble bust of Dr. Davis in Alabama marble. The plaster caste is a very fine likeness. He has made an indemnity contract to have the statue ready by the first of December next that it may be unveiled at the coming meeting of the Southern Surgical and Gynecological Association.

Tuberculosis Talk at Portland.—It was a curious commentary, writes *Charities*, upon the rapidity with which the organized work for the prevention of tuberculosis has taken form in this country, that though that work is now recognized as an important and even necessary function of charitable activity, it was not accorded any formal hearing at the recent National Conference of Charities and Correction, upon a program arranged not more than twelve months ago. It was soon found, however, that among the delegates to the convention were many connected with organizations for the prevention of tuberculosis in different parts of the country and, as was to be expected, the opportunity to talk was not lost by those of our brethren, the corner-stone of whose work is popular propaganda. An informal meeting was accordingly called together at which the addresses were arranged so that each speaker should deal with one phase of the general work, and that the work which had been particularly noteworthy in his city. Thus, Mr. Glenn, the chairman of the meeting, spoke of the fact that in Maryland the medical profession had been the moving spirit in the movement, not merely giving its approval and support after its initiation by laymen, as had been the case in most other cities. The work of the Maryland Tuberculosis Commission had been largely one of research and education, and it was as a part of this work that the tuberculosis exposition had been held recently in Baltimore.

Christopher Easton, deputy superintendent of the Metropolitan Hospital in New York, gave an interesting account of the treatment at the tuberculosis infirmary. Largely, the infirmary serves its best purpose in segregating from the community dangerous cases, and in furnishing valuable object lessons in the proper treatment of tuberculosis to the patients, the thousands of their visitors and to a public becoming more and more intelligently interested in the infirmary. A unique feature of the work at the infirmary is that the deputy superintendent combines with his executive duties the duties of a social secretary, seeing as much of the patients as is possible and dealing individually with a large body of men whose social needs the physicians must ignore or treat *en masse*. The methods of the New York Department of Health and the work of Dr. Hermann M. Biggs in that department were described by Paul Kennaday of the New York committee. The provision of the sanitary code that "tuberculosis is an infectious, communicable disease, dangerous to the public health," the compulsory reporting of cases, the inspection, medical, nursing, fumigating and bacteriological work, the forcible removal of cases, and the dispensary treatment, were described as the combination which had largely helped to reduce the death-rate over forty-one per cent. in the last twenty-one years.

A. M. Wilson of the Boston Committee spoke of the Rutland Sanatorium. This is the first state sanatorium for tuberculosis. It affords Boston the unique oppor-

tunity of adequate sanatorium facilities for all its incipient cases. The close cooperation between the district nurses, the Board of Health and Associated Charities in Chicago was explained by Ernest P. Bicknell of the Chicago Bureau of Charities, and his mention of the home tent treatment, which has there been successfully attempted in a few cases, brought from Mr. Almy, an acknowledgment that he had very little in the way of anti-tuberculosis work to report from Buffalo, where tenement-house matters had been engaging much of their attention. With short addresses by Miss Birtwell, and Messrs. Baldwin, Solenberger and McClain describing conditions in Cambridge, Washington, Minneapolis and St. Louis, and with mutual assurances of mutual aid on the part of those present. It will be noticed that at the next session of the National Conference at Portland, Ore., there will be a special section devoted to this subject with a recognized place upon the program.

Assistant Surgeon Public Health and Marine Hospital Service.—A board of officers will be convened to meet at the Bureau of Public Health and Marine Hospital Service, 3 B Street S.E., Washington, D. C., Monday, October 3, 1904, at 10 o'clock A.M., for the purpose of examining candidates for admission to the grade of assistant surgeon in the Public Health and Marine Hospital Service. Candidates must be between twenty-two and thirty years of age, graduates of a reputable medical college, and must furnish testimonials from responsible persons as to their professional and moral character. The following is the usual order of the examinations: 1, Physical. 2, Oral. 3, Written. 4, Clinical. In addition to the physical examination, candidates are required to certify that they believe themselves free from any ailment which would disqualify them for service in any climate. The examinations are chiefly in writing, and begin with a short autobiography of the candidate. The remainder of the written exercise consists in examination of the various branches of medicine, surgery, and hygiene. The oral examination includes subjects of preliminary education, history, literature, and natural sciences. The clinical examination is conducted at a hospital, and when practicable candidates are required to perform surgical operations on a cadaver. Successful candidates will be numbered according to their attainments on examination, and will be commissioned in the same order as vacancies occur. Upon appointment the young officers are, as a rule, first assigned to duty at one of the large hospitals, as at Boston, New York, New Orleans, Chicago, or San Francisco. After five years' service, assistant surgeons are entitled to examination for promotion to the grade of passed assistant surgeon. Promotion to the grade of surgeon is made according to seniority, and, after due examination, as vacancies occur in that grade. Assistant surgeons receive $1,600; passed assistant surgeons, $2,000, and surgeons, $2,500 a year. When quarters are not provided, commutation at the rate of $30, $40, and $50 a month, according to grade, is allowed. All grades above that of assistant surgeon receive longevity pay, ten per centum in addition to the regular salary for every five years' service up to 40 per cent. after twenty years' service. The tenure of office is permanent. Officers traveling under orders are allowed actual expenses. For further information, or for invitation to appear before the board of examiners, address, Surgeon-General, Public Health and Marine Hospital Service, Washington, D. C.

OBITUARY.

DR. BRYAN G. WILLIAMS, assistant physician Long Island State Hospital at Kings Park, a graduate of Bellevue Hospital, died at sea, May 13, 1904.

DR. CHARLES S. WOODWARD, of 210 East One Hundred and Sixteenth Street, New York City, died at Glens Falls, N. Y., on Sunday, June 26, 1904, after a lingering illness. The *Times*, in speaking of Dr. Woodward's death, says that he was born in Michigan thirty-five years ago, and came to New York when a boy. He took his medical course in New York City, finishing in 1882, and has since been practising in Harlem. He was a member of the New York Medical Society and the County Society.

CORRESPONDENCE.

OUR LONDON LETTER.

(From Our Special Correspondent.)

LONDON, June 11.

INTERNATIONAL CONGRESS ON HOME RELIEF—THE THERAPEUTIC VALUE OF RADIUM—SURGICAL APPLIANCES LEFT IN OPERATION WOUNDS.

AN International Congress on Home Relief—the fourth of its kind—has been held this week at Edinburgh in the work of which the medical profession took a prominent part. There were five sections which dealt respectively with Children; Old Age; Able-bodied Adults and Sick Adults, and Insane and Epileptics. The opening address was delivered by Lord Balfour of Burleigh, Secretary of State for Scotland, who said that the general object of the Congress was to discuss the methods by which help could best be given to their weaker and less fortunate brethren without relegating them to special institutions where recipients of relief were congregated together. He wished it to be understood that the motive of their meeting was in no way antagonistic to the charitable work carried on in hospitals and similar institutions. The independence of the individual citizen in his own home was the ideal organization of a nation, and any system of public relief ought to interfere as little as possible with that organization. Did he go too far, he asked, when he said that the whole practice of their hospitals, infirmaries, provident dispensaries, friendly societies, etc., and even the work of the private medical practitioner among the humbler classes of the population were in a hopeless state of disorganization? Was it too much to hope that the treatment given by hospitals, if properly organized, could be made supplementary to the treatment of the sick poor by their own friendly society doctor or their own medical adviser, who, inasmuch as he knew the home and habits of his patient, was better qualified to advise than the overworked medical attendant in the out-patient department of a great hospital? He dreaded the direction in which they were tending, and expressed the belief that their hospitals could never obtain enough money to meet the growing demand which the present policy tended to invite. No system for the relief of the poor would ever be satisfactory unless there was full and organized cooperation between voluntary agency and public relief. He concluded by urging them to cherish what there was of healthy home life in the community, as family life was one of the most valuable elements in the social constitution of a nation.

In the Section of Children, Miss M. Horn, school manager under the London School Board, read a paper on "Home Relief in Relation to the Feeding of Infants and School Children," with the view of proving that the feeding of children, from the school as a center, was an essentially bad method of relief, but that many other forms of home relief which tended to induce self-respect and independence on the part of parents could be successfully carried out by capable managers with the cooperation of the teachers. One party advocated free feeding of children by the munic-

ipality, and so ensure, as they argued, that the children were not in a state of hunger when in school and could profit from the lessons taught them. Experience went to prove that where they had carried out energetic and enlightened home visiting, no child need fail to obtain relief if it required it; and secondly, that private charity was sufficient to meet the demand for relief in schools. The demand for help was largely an artificial one, and was created in schools where it was known that relief was likely to be freely given. If charitable committees could be established in every school, to promote hygiene, thrift, apprenticeship, and administer relief if necessary, they should then be nearer an ideal system of home relief in connection with school children, than by any system of aid which attempted to meet obvious needs at the expense of serious deterioration of character.

Dr. H. Wright Thomson, assistant surgeon, Glasgow Royal Infirmary Ophthalmic Institute, read a paper on "Home Relief in Relation to Certain Eye Diseases in Children." Educational methods, he said, had tended to promote shortsightedness or myopia, and means should be taken to minimize this. In childhood it was possible by treatment to affect the future course of myopia by (1) wearing glasses; (2) resting the eyes; (3) improving the general health. City children thus affected might be boarded out in the country, where their condition would improve under better feeding. Another disease of the eyes—strumous ophthalmia—was in a large proportion of cases a direct result of bad feeding. Cleanliness and an abstemious dietary were necessary for its treatment.

The Section of Sick Adults was presided over by Mr. Malcolm Morris, who said it should be clearly understood that the duties to the sick poor were not based entirely on philanthropic sentiment and Christian charity, but were dictated by the law of self-preservation. Invaluable as the work inspired by charity had been in the past, and greater still as they confidently believed it would be in the future, the question was essentially an economic one, and must be dealt with as such if a satisfactory settlement was to be reached. In spite of all that had been done in the past few years for the mitigation of the scourge of consumption, we were still only at the very beginning of the campaign. Sanatoria were springing up all over the country, and municipalities were waking up to the duty incumbent upon them of providing for the consumptive poor. That provision, however, was limited to cases still in the early stage when the disease was curable, while for the advanced cases, which formed a large majority of the whole mass of sickness, there was little or no provision. These cases must necessarily be treated either in consumption hospitals or at home. The consumption hospitals, however, could do comparatively little in the face of the enormous numbers of tuberculous sick. The problem of tuberculosis was, therefore, essentially a question of home treatment. Theoretically, the sanatorium was intended only for what were called incipient cases, but, as a matter of fact, incipient cases were very seldom to be found in these institutions, for the simple reason that they were rarely discovered outside. It was in the home that really incipient cases were to be found, and it was there that they must be looked for and dealt with, either by removal to sanatoria or by such applications of the modern treatment by air, sunlight, and hygiene as might be practicable in the circumstances. As soon as the disease was recognized, the patient should, if possible, be sent to a sanatorium, but at present it was only in an insignificant proportion of cases that that was feasible. They hoped, however, that the day would come when every large town would have a sanatorium of its own for the treatment of the consumptive poor. Compulsory notification of tuberculosis was as necessary in the warfare against the disease as the work of the Intelligence Department was in a campaign, and he thought the legislature should be asked to carry that desirable reform into effect. Dr. R. W. Philip, the pioneer of the open air treatment in Scotland, dealing with the same subject, said a complete organization against pulmonary tuberculosis must include for large cities: (1) A home for dying patients, chiefly in the interest of other persons; (2) a sanatorium or sanatoria for selected patients who, with a view to the care of the disease, require a special regime not procurable in their own homes; (3) colonies for the after-life and supervision of patients in whom the disease has been sufficiently arrested to make selected open-air employment feasible and desirable; (4) a tuberculosis dispensary for the treatment of out-patients which should also be the center of an educational propaganda for the instruction of the public in the means of preventing consumption.

In closing the discussion, Dr. Philip moved the following resolution, which was unanimously carried: "That in the opinion of this Section an organized effort against consumption is required. The Section believes that this will be best effected by the establishment of a properly equipped tuberculosis dispensary, under the direction of the municipality or the local authority."

Professor W. Japp Sinclair, of Manchester, introduced a discussion on "The Means of Home Attendance on Parturient Women in Large Centers." He said it was much to be desired that members of the medical profession should be relieved of certain duties in connection with midwifery cases, without appreciably diminishing their practice and its emoluments. Under the present circumstances there was a constant temptation to hurry through with ill-remunerated cases. Would it not be better for the medical profession to assist in a gradual change in the direction of the custom prevalent in Germany, by which qualified men do not assist cases of labor, except among a class considerably higher socially than those from whom they accept an unmentionably small amount of fee, and to leave the poorer classes of patients to the care of really well-trained midwives? The midwife of the present day must be tolerated as long as she continued to exist and a new order could be established only by the fluxion of time, and by the exercise of such influences as could be legitimately brought to bear in the cause of progress. He had formed the opinion that the best hope of establishing a new order of things with regard to the attendance on parturient and puerperal women must rest upon developments from the public lying-in hospitals which were supported by voluntary contributions. The new order of midwife must belong to a higher class socially than the old, and must be better educated and more highly trained.

In the Section of Insane and Epileptics, Dr. Alexander Robertson, consulting physician, Glasgow District Lunacy Board, read a paper on "The Scottish System of Boarding Out the Insane Poor in Private Dwellings." The special feature of the system was the boarding in the houses of strangers of not more than four harmless insane, those houses having previously been licensed by the Lunacy Board on being satisfied that both houses and guardians were suitable. The Act of 1862 permitted four patients to be in one house; but experience had shown that not more than two was generally the best. The risk with the larger number was the development of a modified asylum—isolation of the insane from the family circle. The kind of guardians which he found most suitable for females were elderly widows with a grown-up daughter at home. For men it was always imperative that there should be a man resident in the

house. For the great body of patients who did not require asylum treatment the boarding-out system was the best.

In discussing the paper, Dr. J. F. Sutherland, Deputy Commissioner-General, Board of Lunacy for Scotland, referred to a Bill introduced into the House of Commons the other day by the Attorney-General, Sir John Batty Tuke and Dr. Farquharson, and others. That Bill *inter alia* was to check the early certification of the insane and all the disadvantages it meant to the individual afflicted, to the families concerned, and to enable the medical attendant to place doubtful or temporary cases in private homes and in observation wards without the need of certification. If this Bill became law there would be fewer certifications and fewer inmates of institutions and more relegated to home care.

Dr. J. M. H. MacLeod, of Charing Cross Hospital, is a very shrewd and honest observer, qualities that make his statements as to the results of treatment more trustworthy than those of many who report on the effects of new remedies. He has tried radium bromide in a number of cases of lupus vulgaris, lupus erythematosus, rodent ulcer and epithelioma, and his experience has led him to the conclusion that the chief utility of the agent is in the treatment of rodent ulcer. In the case of small ulcers it acts "almost like a charm," but in those even of moderate size the treatment by X-rays is more practical. In some cases, however, in which the rays seem to lose their power, they may with advantage be supplemented by radium. In regard to epithelioma his experience is disappointing. He is inclined to regard the agent as of little value in malignant disease and urges the necessity of immediate excision, and the postponement of treatment by the various radiation till after operation. In lupus vulgaris radium is a useful adjuvant to the Finsen light and X-rays, but in lupus erythematosus it is of no use. These conclusions substantially coincide with those of Dr. John Macintyre, of Glasgow, another level-headed and honest observer. Yet a few weeks ago, one of our leading chemists, Sir William Ramsay, told a lay audience at the Authors' Club that radium is "an infallible cure" for lupus. When scientific luminaries talk nonsense of this kind, is it surprising that the papers are full of the miraculous effects of radium in all manner of diseases? One feels inclined to say of Ramsay, as Hamlet says of Polonius: "Let the doors be shut upon him; that he may play the fool nowhere but in 's own house."

Only the other day the name of Mr. Stephen Paget, a son of Sir James, came somewhat unpleasantly before the public at an inquest on the body of a woman who had died after an abdominal operation performed by him. A second operation became necessary and it was found that a pair of forceps had been left behind at the first one. The case was made the most of by the newspapers that deal in cheap sensation, and the surgeon's misadventure made the Philistine—in the person of Stephen Coleridge, the antivivisection agitator, with whom Paget has had a good deal of controversy—rejoice exceedingly. Last week an action for malpraxis brought against a lady doctor, Miss May Thorne, was tried and resulted in the lady being mulcted in damages. In this case, too, the patient was a woman, in whose body a sponge was left after an abdominal operation. These cases have exercised the public mind a good deal. In the first case the accident seems to have been due to a faulty method of checking the number of forceps used, and in the other to the remissness of the nurse whose business it was to count the sponges. At nearly all the London hospitals there is a double check system, the instruments being counted by the surgeon and an assistant or nurse before the operation and again immediately afterward. It has been suggested that such accidents offer a field for a new development of insurance, which would enable patients to insure against the risks of surgical operations, and surgeons against damages for accidents which may happen to the most skilful.

SOCIETY PROCEEDINGS.

AMERICAN SURGICAL ASSOCIATION.

Twenty-fifth Annual Meeting, held at St. Louis, Mo., June 14, 15 and 16, 1904.

(Continued from Page 38.)

SECOND DAY—JUNE 15TH (*Continued*).

New Aids in Diagnosis of Surgical Diseases of the Kidney and their Value.—Dr. A. T. Cabot, of Boston, said that no very startling new devices had been inaugurated during the past year. One method had been suggested, however, for obtaining the urine from one kidney without the use of the segregator or ureteral catheter. It consists in washing out the bladder and then massaging the kidney to be tested for several minutes. This somewhat crude method serves an admirable purpose, so far as it goes, the urine probably being expressed from the kidney and pelvis by the handling. The fundamental difficulty in obtaining guiding information from any form of single organ examination lies in the fact that in health there are wide variations in the secretions of the two kidneys. This makes such tests of little value unless they are carried on over a long period of time. He concluded that segregation is of value in determining the presence of diseased kidneys, but that the question of functional power of the two organs should not be carried too far.

Dr. A. D. Bevan, of Chicago, said that there were two points of very special interest in determining the diagnosis of renal disease. He had recently supervised over three hundred cryoscopic examinations and had determined, first, that this method of diagnosis is of absolutely no value whatsoever when applied to the urine, but of very great worth when applied to the blood of suspected cases. The variation in the freezing point of the blood is a very constant factor. The important further deduction from his observations is that anemia varies the freezing point inversely, as does renal disease, and it is the relation between these two factors which must be studied out and applied before cryoscopy can be made available as an important diagnostic aid. X-ray in renal work is at present with the least doubt *the* most important diagnostic aid; practically 100 per cent. of correct versions being returned by it.

A Case of Acute Pancreatitis Associated with Gall-stones.—Dr. James Bell, of Montreal, described the history of this patient, a physician, upon whom he had operated and subsequently reoperated, to remove a stone in the ampulla of Vater, which was occluding the common duct. At the time of the primary operation, which was for acute pancreatitis, the liver and gall-ducts were grossly, at all events, in normal condition. All signs of the trouble disappeared; the patient was well for two years, then he began to show signs of hepatic trouble. The pancreatitis in this case was the first to develop. The final results were admirable.

Treatment of Cleft Palate.—Dr. Truman W. Brophy, of Chicago, made a strong plea for operation in early infancy. He said that the generally ac-

cepted theory that the lip should be united early and the bone left until late was, in his opinion, a great error. He gave a most instructive lantern-slide demonstration the point of which was to show that in cases of cleft palate the parts are not deficient in bone formation. As shown, the point became clear that these children present an abnormal widening of the superior maxillary arch; that the inferior teeth germs close on each side within the upper circle and that the crowding together of the parts in very early infancy can but serve to place the gums in normal relation with each other. The shock of an early operation may justly be considered to be less than a late one, for the reason that the infant's nervous system is less developed than the child's. The bone should always be moved or bent without fracture and to this end it is necessary that the work be done within the first six months of life. It has been shown conclusively that the constant impact of the wedge-like lower jaw drowe asunder the already separated upper fragments; this alone was a definite argument for early operation.

Dr. A. H. Ferguson, of Chicago, said that while he agreed with Dr. Brophy in that operation should be done at an early age, he believed that infants bear the shock of a major operation badly and for that reason the old plastic methods should be employed, so modified as to move a small rather than a great mass of bone to close the defect.

Dr. George Tully Vaughan, of Washington, said that he believed Dr. Brophy's operation to be founded on fundamentally correct principles and that its author had conferred a great benefit upon mankind.

Dr. Brophy in closing, said that he considered the lateral incisions unnecessary and that all such cuts were open to the serious objection that they too frequently destroyed the continuity of the tensor-palati muscle, thus giving a clumsy palate, often associated with defective hearing. His mortality in over 300 cases had been below three per cent.

The Evolution of Surgery.—Dr. J. E. Mears, of Philadelphia, spoke of the development of surgery from the earliest days to the present epoch. He said that, broadly, the subject was divisible into three great epochs: the first extending from the unknown past to Ambrose Paré: 1517-1590. This period was terminated by the introduction by this most remarkable way of the ligature for hemostasis. The second period ended by the introduction of ether at the hands of J. C. Warren, while the third and greatest was marked by the discovery and adaptation of antiseptics by Lister; 1860-1875. He cited the oft-forgotten fact that a great deal of very good surgery was done by men who lived and practised centuries before Paré. He alluded to the ingenious devices for and methods of teaching along the time-honored paths: wind, phlegm, bile, etc. Among the Hindus the practice was not differentiated to any wide extent, the priests practising surgery or medicine with equal freedom. The tombs of the Egyptians portray the development of the healing art in that wonderful country with clearness and precision. The Greeks being essentially warlike, turned early to find means for healing the wounds of war, but as no dissection of the dead was allowed, progress naturally was exceedingly slow or, indeed, it may be said to have been nil. With the development of the Alexandrian school, however, and the advent of Herophilus, the art developed rapidly into the most astute of sciences. Due entirely to the limitations put upon them by their religion and not to any fundamental lack, the Arabians contributed but little to the development of medicine and surgery, but helped in a very general way in preserving for western civilization the knowledge which had been brought to such a stage of perfection at Alexandria. Ambrose Paré began as a barber-surgeon's assistant, but worked on and on until he published some of the most monumental works in all medicine. The idol of the army, particularly of the rank and file, he was obliged to special finding of the court to justify the use of the ligature by reference to ancient authorities. The influence on the development of surgery of military power cannot be estimated. This can be traced well in the warlike State of Prussia where, until a very recent date, the surgeons were obliged to shave the officers,—a sorry position for one who shouldered such responsibilities as the regimental surgeon. Lister's work transcends all others, for the reason that before the days of chloroform and ether, in the times of Homer and earlier, certain forms of anesthesia were by no means unknown. Mandrake and hyssop were used to solace suffering centuries before Christ. For this reason it can truthfully be said that anesthetics—inestimable boon that they are—stand second to antiseptics. Like all else, the modern practitioner is the product of evolution; from the ear-borer and blood-letter of Paré; from the regimental surgeon of Lister, has developed the finished surgeon of to-day.

Professor S. Pozzi, of Paris, spoke by invitation on the relation of the old Parisian hospitals to the development of surgery. He said that the old Hôtel-Dieu was, of course, the representative of all that is old and venerable in medicine. It was destroyed by fire some forty years ago and most unhappily was rebuilt on the old Roman lines. Now the tendency in France was to erect hospital buildings of a more temporary character. He paid a graceful tribute to the American system of ventilation and stated that he had introduced it in his new Hôpital Broca.

A Mechanical Device for Gastric and Intestinal Anastomosis.—Dr. F. B. Harrington, of Boston, showed his well-known segmented ring which has proved so useful in exploiting this work. The segments are of aluminum, so collared that they brace against each other and thus maintain a circular form when tied together with a bit of catgut. A handle of convenient length passes through the ring to be screwed fast in the inner circle after passing through a segment diagonally opposite. This handle serves admirably to hold and steady the parts during introduction. The ring, as usually made, is seven-eighths of an inch in diameter and breaks up into segments of hardened aluminum, each weighing ten grains. The handle is of steel. At the end of twenty-four hours the ring is held in place more securely than at the time of its introduction on account of swelling. The author showed a set of chamois-skin models of the button *in situ*—a method of invaluable aid in teaching students the various technics. In shape the ring is not unlike Mayo-Robson's bobbin and its manner of introduction is similiar. In conclusion the speaker said that the advantages of the segmented ring lay in its safety, in the ease and speed of its introduction and in its cleanliness. It can be made by any manufacturer, quite unlike the Murphy button, not being dependent for its safety upon a delicate system of springs. It cannot fail to collapse as it is held together by a frail and absorbable strand of catgut. It affords protection to weak spots, specially at the mesentery until danger of leakage has passed. Histological specimens show

that the process of repair during use of this button is just as satisfactory as occurs after suture.

Dr. J. W. Draper Maury showed models of a "Twine Triangular Stitch," such as is employed at the Surgical Laboratory of Columbia, in making experimental gastro and entero-enterostomies. He presented a specimen and demonstrated the method of introducing the twine from a chart. Twine, he said, had recently been substituted at the laboratory for the McGraw ligature and had been shown conclusively to cut through as surely and at about the same rate as the elastic. He said that by using a triangular form of stitch control could be had over the size of the area punched out. In the case of the McGraw stitch a simple linear cut is made.

Dr. A. J. Ochsner said that he shared with most other surgeons the objection to the use of any mechanical contrivance to facilitate the connection of two hollow viscera, but as a matter of fact he believed that their employment was a safeguard to the patient and was therefore to be encouraged. He had long since become convinced that the Murphy button was open to most serious objection. In his last 87 cases he had had recourse to the elastic ligature and had had better success with it than with any other form of technic. In reference to the new button of Dr. Harrington, he said that in its employment he saw the very distinct advantage, viz., that it is sure to have a patent lumen.

Dr. Harrington, in closing, spoke of the action of the muscular waves of the stomach carrying as they had been seen to do, the fragments of his button toward and into the open pylorus.

Results with the Use of Radium.—Dr. Robert Abbe demonstrated a very powerful specimen of this element and presented a complete series of casts, photographs and radiograms which demonstrated the experiments he had been carrying on. He showed among other things the results of his experiments on the effect of exposure to radium rays plant life growth is markedly retarded. In like manner exposure to radium interferes with normal development of worms. Under the rays the worm lives, but remains a worm.

Therapeutic Value.—On small superficial epitheliomata the rays work well. They destroy, not as a cautery, but by some unknown subtle power. This power is a factor to be reckoned with, but as it is ten times more efficient than the Finsen light so as the X-ray tenfold the worth of the radium ray.

Dr. W. W. Keen, of Philadelphia, in discussing this paper said that he had employed radium in 22 cases, and that not in a single one was there any appreciable result save that the pain was stayed. He had temporarily relieved a case of tic douloureux. Possibly it was the type (German) of radium he used, but its strength had been reported to be 1,200,000.

Dr. Abbe, in closing, said that he never had intended to suggest the matching of radium against the X-ray. He reported what he did simply for scientific and pathological interest.

Gastrostomy for Esophageal Stricture.—Dr. James H. Dunn, of Minneapolis, said that Dunham's device of string swallowing enables the operator to pass almost any stricture. Retrograde dilatation is not to be condemned, however. Its employment dates from the early days of Loreta's work. The operation is usually done in two stages because, as is well known, strictures soften from rest. The author considered Abbe's method combined with Dunham's as the safest and best. Dilatation should always be carried far beyond the normal size—the common instruments of the shops having no value because of their small size. He reported the results in three interesting cases.

Dr. Abbe said that even with Dunham's admirable device the combination of methods as suggested by Dr. Dunn seemed to him too complicated. The essential of the string operation is that the stricture must be put on tension, otherwise the twine will not cut. His first case, operated on twelve years ago, has had no recurrence, being to-day alive and well.

Dr. Dunn, in closing, said that he believed the indications for retrograde dilatation to be, first, when no filiform could be passed; second, in all difficult strictures which cannot be treated except by much difficulty from above. Many people have died as a result of ill-fated attempts to pass a dilator from above.

Removal of Upper Jaw for Osteosarcoma.—Dr. S. J. Mixter, of Boston, exhibited the photographs and radiograms of a case which was truly of amazing characteristics. The patient was a man who for the past six years had been confined in an attic room unable to venture abroad because of the frightful looks and nauseating odor of his whole face. The mouth was crowded into the neck—one eye was entirely destroyed by the growth. Its removal constituted a surgical triumph the like of which can seldom be seen.

A Contribution to the Surgery of Nerves.—Dr. Charles A. Powers, of Denver, said that his paper represented a none too satisfactory effort to bring the subject of nerve surgery up to date. Probably the very nature of the lesion and its after history, coupled with the fact that many papers had been written by Europeans and published in little known journals. In all he had been able to collect and study 56 cases. The bridging of defects by catgut and tubularization have both been shown to be equally faulty. In conclusion he said that it was hard to say what should be done; neuroplasty, bone resection or implantation are always at hand, transplantation should be abandoned and prognosis in every case should be most guarded.

Final Result in Secondary Suture of Nerves.—Dr. Emmet Rixford, of San Francisco, reported three cases which he had sutured six, four and two years ago, respectively. Ten weeks after severance of the ulnar he had sutured that nerve and in a year the functional result was perfect. The second case was that of a musculospiral paralysis also eight weeks after the primary injury. So much retraction had taken place that he was obliged to shorten the humerus. In six months function began and from that time on its return was wonderfully rapid. The third case was also sutured eight weeks after the primary injury. It was the facial and much of the mastoid had to be cut away before the ends could be found. Secondary suture differs from primary by being very much more complex, but its success, when accomplished, demonstrates that degeneration takes place whether primary suture has been done or not. He concluded that secondary suture is but little inferior to primary. A reasonable delay should not discourage from making an attempt to reunite the cut nerve, but in the case of a suppurating wound this should not be attempted until all signs of infection have passed, pus having a most deleterious action upon function restoration.

Dr. Willard said that, as in the case of bone transplantation so with nerves, a very young animal

should be used. Decalcified bone tunnels seem to guide the outgrowing nerves.

Dr. Powers, in closing, said that he recalled the case of a negro upon whom he had sutured the musculospiral. A very large keloid, which involved the nerve developed, necessitating reoperation. The result was perfect and continues so at the end of three years.

Operation for Primary Carcinoma of the Liver.—Dr. Leonard Freeman, of Denver, spoke of the rarity of the condition—the single growing nodule being, of course, the only one suitable for surgical intervention. In his case he had used the gauze strips to prevent hemorrhage and had found them to be satisfactory except when it came to removing them. This was accomplished in the end without difficulty.

Dr. W. W. Keen, of Philadelphia, said that the control of hemorrhage in these cases is the all-important consideration. He considers the cautery to be the most valuable aid at hand; it exposes the big vessels which may then be tied and at the same time destroys the small one.

Dr. L. L. McArthur, of Chicago, spoke of the difficulty of positively saying that a given enlargement was solitary. He had found the Mikulicz sack serviceable in controlling hemorrhage.

Dr. Freeman, in closing, said that in spite of Dr. Keen's good fortune with the cautery he would continue to use the gauze strips.

Third Day—June 16th.

Thyriodectomy for Exophthalmic Goiter.—Dr. Charles H. Mayo, of Rochester, Minn., said that over 1,400 books and monograms had been written on this subject, particularly upon its bearing on the question of internal secretion. Tachycardia he has come to consider the one cardinal symptom of the disease, but it may not appear until late in the course of the trouble. In the treatment of the condition the internist and the surgeon are drifting apart. Few cases are operated on until after they have submitted to years of unsuccessful medication. The opposing action of the thyroid and the suprarenal glands serve to maintain the equilibrium of the blood pressure. It is therefore not astonishing that the heart should early feel the change. As is well known, the two procedures now in vogue are thyroidectomy and section of the cervical sympathetic. He has used the X-rays in ten cases of goiter and, as should be expected from the known action of the ray on lymphatic tissue, they were much benefited. Of 128 operations on the thyroid, 40 were done for the relief of exophthalmic goiter. For anesthetic he has used cocaine, chloroform and ether, the last being preferable.

Thyroidism.—This symptom is so alarming because of its high fatality he considers due to absorption of wound serum—the area should therefore be as freely drained as possible and full quantities of salt solution should be given to prevent such absorption. Fifty per cent. of the 40 cases were entirely cured by gland resection; 25 per cent. were cured in time; 25 per cent. were improved. Belladonna should be exhibited before operation and no case in extremis should be accepted from the internist.

Dr. Ochsner, of Chicago, said that avoidance of pressure on the gland or rough manipulation of any kind whatsoever was to be avoided. Before attending to this detail he had lost two cases. The general anesthetic is not the cause of death, but it enables the surgeon to be rough—hence its danger.

Dr. Rixford, of San Francisco, said that he had operated on 12 or 14 cases without mortality. He always uses weak cocaine infiltration. One-half of his cases were drained—the remainder did just as well. All showed moderate rise of temperature. He considers thyroidism more common in the so-called primary goiter.

Dr. Mayo, in closing, said that too rough handling is engendered by a small incision; it should be made free.

Primary Splenomegaly; Splenectomy.—Dr. A. F. Jonas, of Omaha, reported a case which was of particular interest, first because of the rarity of the condition and second, because of the leaving in the abdomen one or more of the accessory spleens, five of which were found grouped about the pedicle. This is the twentieth case reported. At time of removal the hypertrophied organ weighed seven and one-half pounds.

Dr. Mixter, in closing the discussion of his case, said that it simply showed what could be done by taking desperate chances and by making use of osteoplastic flaps for the repair of defects.

Gall-stones in the Common Bile Duct.—Dr. S. H. Weeks, of Portland, reviewed the technic of the subject with special reference to diagnosis.

Dr. Richardson said that to his mind the essential of success in gall-bladder surgery lay in free and long-continued drainage. Brilliant results have been obtained by immediate closure, but this offers greater chance for disaster.

Dr. Rudolph Matas, of New Orleans, said that in most cases of fracture of the jaw the temporomaxillary joint need not be immobilized. He demonstrated a new form of intrabuccal splint which was characteristically ingenious. Since most of these fractures occur in adult males it is possible by having the buccal portion made of a malleable metal soft enough to mold, to use a single splint for an entire service. The apparatus he exhibited showed the tooth-marks of many patients on whom it had been used with admirable success. It combines the precision of an interdental plate with freedom from a dentist. The splint is not designed for simple cases which respond to simple conditions, but is meant to meet complicated conditions. It is so easy of application that anyone can apply it. The patient, once the splint is in place, may drink and speak much more freely than with any other form of splint and, what is of at least equal importance, free disinfection of the mouth is possible.

Dr. A. H. Ferguson, of Chicago, showed a patient on whom he had early last March done straight nephrotomy for the relief of chronic interstitial nephritis. The pathological examinations had been most carefully done—the urine showed granular and hyaline cast. Less urine, on catheterization, came from the left organ, so that was chosen for section. The renal pelvis was drained for eight days, and in eighteen days the output of urine had risen from 18 ounces to 60. One very interesting point in this case was the sudden feeling of relief which came to the man immediately after operation.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, held March 9, 1904.

The President, O. H. Schultze, M.D., in the Chair.

Period of the Greatest Accumulation of Tetanus Toxin in Broth Cultures.—Dr. Cyrus Field read a paper on his experiments on this subject. In preparing toxin for the purpose of immunizing horses to tetanus,

he said that it was important to obtain as strong a toxin as possible, as there was then less volume of bouillon to inject. In preparing toxin for this purpose at the Research Laboratory of the Department of Health, it was the custom to grow the organism for nine or ten days in flasks holding about two liters of bouillon which had had 12 c.c. of normal NaOH solution added to it after having been made neutral to litmus. The bouillon was covered with a thick layer of paraffin about one-half to three-quarters of an inch thick. This sealed it off and gave a practically anaerobic condition. For every liter of bouillon about 20 c.c. of an old tetanus bouillon culture was added before the paraffin had hardened. The strength of this routine toxin was found to vary greatly, one week a $^1/_{1000}$ of a c.c. being the minimum lethal dose, perhaps the next a fiftieth or even a tenth. Thinking that perhaps it was the length of time for which the culture was grown, Dr. Field determined to take a sample of toxin from the flask each day and test its toxicity. For this purpose, alboline, which is a liquid paraffin, was used instead of paraffin to seal off the media. This permitted the introduction of a pipette and the drawing off of any amount of culture without disturbing its anaerobic condition. A sample of the culture was removed each day at the same hour, a portion being titrated to determine the degree of acidity and the rest passed through a Berkefeld filter; a portion of this filtrate was also titrated and the rest was used to make up the various dilutions for injection. Tetanus toxin is such an unstable compound that one has to determine its minimum lethal dose by making all the possible dilutions and injecting them at the same time, as the following instance will show. Having filtered two liters of a culture Dr. Field tested it and found that its minimum lethal dose at that time was $^1/_{500}$ of a c.c. The next day, it being needed for purposes of immunization, it was again tested before being sent to the veterinarian, and at this time the minimum lethal dose was $^1/_{50}$ of a c.c. The titration in all this work was done with a twentieth normal NaOH solution, phenolphthalein being the indicator. The method of determining the minimum lethal dose was as follows: The filtered bouillon was added to sterile water in various dilutions; for instance, on the first day five dilutions were made up, one c.c. of each containing respectively $^1/_{10}$, $^1/_{25}$, $^1/_{50}$, $^1/_{100}$, and $^1/_{250}$ of a c.c. of the bouillon culture. One c.c. of a dilution was injected into the muscles of the hind leg of a three hundred gram guinea-pig. If the pig died in four days with symptoms of tetanus poisoning he was considered to have received a fatal dose of toxin, so that the pig dying from the effect of the highest dilution was considered to indicate the minimal lethal dose of that toxin. As will be seen, it required a large number of guinea-pigs to carry out the testing of a culture in this manner. The acidity of the unfiltered sample was always much higher than that which had been drawn through the Berkefeld filter, Dr. Field's explanation for this being that the bouillon which had not been filtered contained a great amount of sulphureted hydrogen which is one of the gases formed by the tetanus bacillus in its growth. This gas is acid in its reaction. When the bouillon was drawn through the Berkefeld filter it entered a vessel from which most of the air had been exhausted, and therefore any gases which might be held in solution were rapidly drawn out of the bouillon. When this gas is sulphureted hydrogen, giving the bouillon an acid reaction, there was naturally a great lessening in the degree of the acidity after it had passed out. To determine whether or not this explanation would hold, Dr. Field took some water which contained large quantities of sulphureted hydrogen, and determined its degree of acidity. It was found to require 3 c.c. of a twentieth normal NaOH solution to neutralize it. This was passed through a Berkefeld filter into a vessel in which the air had been exhausted, and was allowed to remain there five minutes. It was again withdrawn and its acidity determined. This time only 2.2 c.c. of the same solution were required to neutralize it. Tetanus toxin remained in a vacuum much longer, as a rule, than five minutes, so it would seem that the high acidity in the unfiltered sample was due to the bouillon containing a large quantity of sulphureted hydrogen in solution.

Dr. Field's conclusions drawn from this work were as follows: (1) On the average the best results will be obtained if the culture be grown only six or seven days in the incubator and after filteration be kept in the ice-box. (2) No toxin should be used after fourteen days have elapsed from the date of inoculation. (3) As a rule, the degree of acidity of the unfiltered bouillon varies directly as the amount of toxin formed, but sufficient work has not been done to permit any definite statements.

Dr. Field said that at some future time he intended to test the effect of the toxin before filtration to see if it, too, was affected in any manner by the vacuum, and also to test the power of an old, reduced toxin to neutralize tetanus anitoxin.

Calcified Thrombus of the Inferior Vena Cava.—Dr. George P. Biggs presented this specimen. He said the patient from whom the specimen was obtained was unconscious when admitted to the hospital, and died three days later without giving any history. He was a well-nourished man, an engineer, aged sixty-one years; a native of the United States. At post mortem the immediate cause of death was found to be fracture of the skull with extensive cerebral laceration. The vessels at the base of the brain were very sclerotic. Fibrous puritic adhesions were numerous. Left ventricle of the heart hypertrophied. Valves normal in structure; but there was relative aortic insufficiency. The entire arch of the aorta was uniformly dilated to a diameter of about 5 cm. and its wall very much thickened, measuring 6 to 10 mm. The enlarged arch made moderate pressure on the right auricle, superior vena cava, trachea, and pulmonary artery. Sclerotic changes were marked throughout the aorta and there were numerous areas of calcification. Spleen was normal in size and consistency, but firmly adherent to surrounding organs. Right kidney larger than normal, left slightly smaller than normal; both presenting similar lesions aside from variation in size; viz., moderate chronic nephritis with numerous small cicatrices.

Microscopical examination showed moderate amyloid degeneration of kidneys and spleen. Liver normal in size and general appearance except for a few small cicatrices. The foregoing lesions are mentioned chiefly because of their strikingly syphilitic nature and manifestations.

The nature of the specimen demonstrated by the speaker was not appreciated until after its removal from the body, and changes in the circulation could not be accurately determined. Distinct enlargement was, however, noted, in the azygos, iliac and renal veins.

The inferior vena cava from its beginning up to the level of the renal veins was completely occluded constituting a hard, absolutely rigid column firmly adherent to the aorta. The diameter of the vena cava is one and one-half to one and three-quarters cm. In the center of it is a small, calcareous rod-like portion, one-half to three-quarters cm. in diameter, extending throughout. The balance of the structure is chiefly fibrous tissue, all traces of the thrombus having been replaced thereby. One naturally thinks of the syphilitic character of some of the other organs in connection with the etiology.

Case of Unilateral Thrombosis of Cerebral Veins.—The following condensed record of this case is of interest, partly because of inability to harmonize the symptoms with the lesions. The patient was a male, aged twenty-seven years, a native of Ireland, single, mattress maker. He gave a history of syphilis four years ago. Moderate drinker. Two weeks ago noticed weakness and anorexia. Pain in right axilla; general aching pains. After five days was able to be out. One week before admission had a severe chill followed by fever and pain on right side. Cough with mucopurulent expectoration, later becoming blood-tinged. Signs of consolidation in the lower part of the right upper lobe and apparently in the upper part of the right lower lobe. On the third day after admission he looked septic and it was suspected that there might be some pus in the right pleural cavity. A needle was inserted with negative result. Immediately following this aspiration, the patient became pale, pulse imperceptible, respiration labored. After stimulation, considerably improved. On the same day there is an entry on the chart of slight nystagmus of the left eye. At 5.30 the same afternoon the nurse reported a right-sided convulsion lasting about two minutes. On the following day (the fourth day after entrance to the hospital), another slight right-sided convulsion, lasting about half a minute. On the fourth day of the man's stay in the hospital it was recorded that since the previous afternoon the patient had been unable to move the right arm or the right leg, or left side of the face. The right arm and leg were rigid. Knee-jerks seemed more active on the right than on the left side. Patient semi-comatose. On the morning of the fourth day, it was impossible to make the patient move the left arm or the left leg; the right side of the face was movable. On the fifth day, the left side of the body was only slightly rigid, and the left hand responded to stimulation. On the sixth day, patient moved both arms on irritation. Pulse weak, respiration labored. Died on the seventh day after admission, two weeks after definite chill with pneumonic symptoms. Temperature 104° F. on admission, inclined to become lower, reaching as low as 100° F. the day before he died, rising the night before death to 104° F. Respiration varied from twenty-four to thirty-six. Leucocytes, 13,800. Embolism was thought the probable explanation of the cerebral symptoms.

At autopsy numerous old adhesions were found over the liver, also pleuritic adhesions on both sides. Heart normal, except that the aortic cusps presented a slightly roughened appearance suggesting acute endocarditis, although the lesion was not marked, also a nodular area of thickening of one of the cusps, three mm. in diameter. After the pulmonary vessels of the right lung had been opened very freely with scissors, three small portions of ante-mortem thrombi were found. Their origin could not be determined but they must have been loosely attached in some branch of the pulmonary artery or vein. No other thrombi were found in the lungs. There was considerable bronchopneumonia of the right lung, particularly in the region in which the physical signs had been heard, and also fairly extensive chronic interstitial pneumonitis of the right lung. A small area of obsolete tuberculosis was found in the right apex. In the kidneys there was parenchymatous degeneration with a few hyaline casts in the tubules of the pyramids. The most noticeable lesions after the removal of calvarium and dura were areas of diffuse hemorrhage of the pia over the right hemisphere, adjacent to and extending a distance of about 4 cm. from the great longitudinal fissure. There were no clots of blood. Veins over the right hemisphere were distended and in contrast with those over the left hemisphere. Convolutions on both sides were moderately flattened.

Having in mind the possibility of emboli or thrombi at the base of the brain, very thorough search was made, the vessels being carefully watched as they were severed and after removal of the brain by careful dissection. There was absolutely no trace of thrombi or emboli. The right Sylvian artery did not appear to be especially engorged and there seemed to be nothing especially noticeable about the arterial supply as far as the large vessels on the right side of the brain were concerned. On opening the longitudinal fissure a parietal thrombus was seen loosely attached to the right wall. It was 3 cm. in length and located midway between the anterior and posterior ends of the sinus. The terminal ends of the right cerebral veins emptying into the sinus in the region of thrombosis contained occluding thrombi, one cm. in length. Beyond the thrombi the veins were distended with fluid blood. These thrombi corresponded with areas of hemorrhage noticed in the pia. Parietal thrombi were found in each lateral sinus, also. Apparently nearly all of the right hemisphere above the level of the roof of the lateral ventricle was softened, but much of this must have been the result of pronounced edema as the appearance of the hardened specimen does not bear out the original impression. Softening is limited to the regions of hemorrhage, most of which correspond with hemorrhages in the pia. These areas of cerebral hemorrhage associated with evidences of softening have a curious outline, often following the irregularities of the cerebral surface as a cortical zone 3 to 7 mm. in thickness. Depth of involvement thus depends partly upon the depth of the sulci. These areas of hemorrhage are entirely in the right hemisphere, chiefly near the great longitudinal fissure. They are 1 to 3 cm. in diameter, and the intervening tissue is fairly normal. No evidences of such lesions are seen in the left hemisphere.

The microscopical appearances of the cerebral tissue are very confusing. In the first place there are evidences of a probable syphilitic lesion in the form of hyaline degeneration of some of the vessels. Then there are other vessels in the regions of softening and hemorrhage, which are occluded with thrombi, some of them fibrinous, some rich in leucocytes. In some instances the perivascular spaces are filled and the surrounding tissue infiltrated with small round cells; in other instances there is no infiltration of surrounding tissue. The inflammatory infiltration is a marked feature in many parts of the involved tissue. Hemorrhages are very numerous, at times very closely related to the thrombosed vessels and at other times hemorrhages are found about vessels which show no distinct lesion. In places, chiefly in the sulci, the pia shows slight round cell infiltration and endothelial proliferation. The question naturally had arisen as to the correct explanation of the lesion. Grossly, the only demonstrable interference with circulation was in the cerebral veins where it was very distinct as shown by the engorgement of the veins beyond the thrombi. The arteries, so far as it was possible to trace them by dissection, did not contain thrombi or emboli, and none have been found in the sections. Dr. Biggs wished very much to have some expression of opinion as to the sequence of events and nature of the lesion.

Aneurism of the Aorta.—Dr. Francis C. Wood presented this specimen. He said that as a rule pathological specimens were not interesting on account of their size; but he had an opportunity of removing a large aneurism from a patient which had excited some interest, and he thought the members of the Society might like to see the extent to which such a growth

might develop. It had been removed from a large and powerfully built man, about forty years of age, who had entered St. Luke's Hospital with an aneurism which had already eroded one of the ribs. He had symptoms of aneurism and the history of syphilis which so often goes with it. He was supposed to be in a dangerous condition, so much so that upon asking for an X-ray picture it was said that the man was moribund and could not have the picture taken. He survived this moribund condition, however, for four months, and was a comfortable, cheery member of the hospital wards. As the aneurism grew larger, it did not seem to produce much discomfort. At the time of autopsy, it projected forward four inches from the anterior surface of the right chest. It seemed as if it would burst at any moment. It had eroded the border of the sternum and extended to the axilla. The ribs were eroded from the first to the seventh and were included in the mass. The lung was laterally compressed, and the pleural cavity contained a small amount of blood where the aneurismal sac leaked. There were also small hemorrhages under the muscles of the chest. The heart had remained comparatively small for so large and powerful a man. The opening of the aorta into the aneurism was closed by a clot. The patient had practically undergone a spontaneous cure, as very little blood could be obtained from the aneurismal sac. In a few weeks he might have recovered.

Primary Epithelioma of the Bronchus.—Dr. O. H. Schultze presented specimens from a case that was diagnosed clinically by Dr. I. Adler as Primary Endothelioma of the Lung. He was indebted to Dr. Maurice Packard, who treated the case, for the clinical history. The patient was a male, fifty-four years old; single; cigar-maker; an inveterate smoker. Family history of arteriosclerosis; no evidence of tuberculosis, syphilis, or alcoholism. Two years before he had had a cough which though alleviated by treatment had never entirely left him. There were no night-sweats; no loss of flesh or strength; no hemoptysis at this time; no dyspnea. The cough during the last two years had gradually become worse and about eighteen months before had been accompanied with profuse mucous expectoration. Dyspnea had become very troublesome and he suffered from pain localized in anterior right side of chest and increased on deep breathing. Sputum was examined for tubercle bacilli with negative result. He was sent to the South but as he did not improve he returned. The cough became more distressing and on many occasions a considerable amount of blood, as much as a cupful, was brought up. Even after these hemorrhages he did not lose weight, nor was his temperature higher than normal. There was flatness on percussion over upper and anterior part of right side of the chest and the veins over this region were prominent. Death occured suddenly with profuse hemoptysis.

Autopsy.—The right pleural sac contained about one quart of blood-stained serum. The anterior surface of the right upper lobe was intimately adherent to the costal pleura which was removed with it. Larynx, trachea, bronchi, lungs, heart and vessels were removed together. A firm tumor, 5 by 3 cm., involved the posterior wall of the right bronchus, the bifurcation of the trachea, and the beginning of the left bronchus. The bronchi, especially the right, were partially stenosed and ulcerated. Immediately below this mass a bronchial lymph-node about 1.5 cm. by 3 cm. was found almost completely infiltrated with new growth. The growth extended along the bronchi into the right upper lobe to its anterior and internal surfaces, where the pleura was intimately adherent to the pericardial sac. Dense infiltration of the growth surrounded the pulmonary vein and the superior vena cava. The lumen of the superior vena cava and that of the pulmonary vein presented mere dimples with radiating longitudinal folds of the vessel wall when viewed from the auricles. The lumen of the right pulmonary artery was narrowed to 5 mm. Sections of the growth throughout the lung were firm with the exception of areas of erosion into the bronchi, evidently the source of the hemorrhage. The middle lobe presented firm consolidation of yellowish white color and flat on section. There were scattered small metastases in the pleura and about the bronchi of the right lower lobe which was compressed by the fluid in the pleura, in the pleural surface of the diaphragm and throughout the left lung. A few isolated metastases up to 5 mm. in diameter were found in a "horseshoe" kidney. The microscopical sections presented showed the same structure throughout, variously shaped islands and strands of cells without intercellular substance, imbedded in a stroma of dense fibrous connective tissue. In these islands the outer cells were polygonal with large vesicular deeply staining nucleus and basophilic protoplasm. Towards the center the cells became flatter, stained more distinctly with eosin and their nuclei stained lighter with hemotoxylin. Concentric arrangement of these flattened cells were indistinct in many places. With Weigert's stain granules and plates of keratohyalin were found. In many islands and in the small metastases, the outer cells presented evidences of growth and infiltration of the surrounding tissue while the inner cells showed progressive loss of structure, coagulation necrosis. The ulcerated surface of the tumor in the wall of the bronchus presented a hemorrhagic granulation tissue. Smooth muscle fibers of the wall of the bronchus could be traced through the tumor.

Adrenal Tumor with Metastases.—Dr. Schultze also presented these specimens. The patient from whom the specimens were obtained, a man fifty-two years of age, had died in Gouverneur Hospital forty minutes after admission. He was suffering from intense dyspnea, no pulse could be felt, and he presented signs of edema of the lungs. The immediate cause of death was excessive edema of the lungs, dilatations, and fatty degeneration of the heart, due to secondary pernicious anemia in turn dependent upon malignant new growths. The left adrenal presented a tumor occupying nearly the entire organ which was symmetrically enlarged to four times its normal volume. The right kidney was almost entirely replaced by a large growth, in volume nearly eight times that of the normal organ, only a small portion of the organ being recognizable. The growth extended through the renal vein into the inferior vena cava, distending it to twice its normal size, as far as the liver. The pelvis, ureter and bladder contained blood clots. The lower epiphysis and adjoining portion of the shaft of the right femur was increased in size to four times the volume of the left. Absorption of bone had advanced to such a degree that the mass was easily broken from the rest of the shaft, and sections through the mass were readily made with the knife. Numerous isolated metastases were found in pulmonary pleura and about the bronchi also in the left kidney.

Microscopical slides from all the growths were presented. The structure showed a reticulum of thin-walled capillaries, the spaces occupied by large polygonal cells whose nuclei stained intensely, the protoplasm very faintly. In the adrenal, kidney, and femur, numerous giant cells were found with central, close arrangement of the nuclei, probably produced by agglutination of cells. In the metastasis in the vena cava, the cells were compressed and fusiform and the vascular reticulum was less distinct. The structure corresponded to that

of the adrenal cortex. The tumors have been described in the adrenal as struma adrenalis or suprarenalis in the kidney, and elsewhere as hypernephroma, adrenaloma, or perithelioma. The kidney tumor might have originated from an embryonal adrenal rest.

Intraperitoneal Hemorrhage from Adenocarcinoma of the Liver Secondary to Adenocarcinoma of the Gall-bladder.—Dr. Schultze also presented slides from this case. The patient, a laborer, forty-three years of age, had died suddenly twelve hours after admission to Bellevue Hospital. Dr. Samuel A. Brown had kindly furnished the following clinical notes. The patient had lost thirty-eight pounds during the last three months. One month before admission it was noticed that his eyes were yellow; the condition was progressive with emaciation, weakness, and loss of appetite. Five days before admission he began to have acute pain on the right side over the liver, increased on pressure and on taking a deep breath. Temperature on admission, 101° F.; signs of cardiac insufficiency and acute perihepatitis. While on bed-pan, endeavoring to defecate, he toppled over and died within an hour.

Autopsy.—Two quarts of blood found in the peritoneal cavity. The source of the hemorrhage was found in a laceration of the capsule of the liver communicating with a large hemorrhagic and softened metastasis. The liver was considerably increased in size and filled with numerous large metastases, hemorrhagic and softened. The superior surface of the gall-bladder was intimately adherent to the liver and presented a papillary growth on its mucosa, infiltrating its walls and the liver. The retroperitoneal lymph-nodes about the head of the pancreas, pylorus, and hilus of liver were considerably increased in size, infiltrated by new growth, hemorrhagic and softened. The retroperitoneal connective tissue was infiltrated with blood, pushing the pancreas forward. The entire mass was about the size of a man's hand. The pancreas was normal. Microscopical slides of the primary tumor and metastases were presented. The structure was that of adenocarcinoma with high columnar cells, in places arranged in tubules, in others irregularly infiltrating the surrounding tissue. Extensive necrosis and hemorrhage were apparent.

Dr. Noyes said that three or four years ago he had presented to the Society a large tumor of the liver of adenomatous nature which, when put under the microscope, proved to be nearly identical with suprarenal gland tissue. It had caused some discussion and a marked difference of opinion, some of the members believing it to be simple ordinary adenoma, others believing it to be metastatic deposits of the ordinary cells of the suprarenal gland in other organs; but the speaker thought it identical with the specimen shown by Dr. Schultze. It was one very large tumor mass which, seen in the specimen alone, would have been taken for suprarenal capsule if it had not been known where it came from. No primary growth was found in the suprarenal gland.

Dr. Harlow Brooks said that it was most interesting to study these cases and to try to find out what primary tumors of the lung were and where they started. He had studied three cases of so-called primary endothelioma of the lung, two of them so named with his half-hearted consent, and one with his vigorous opposition; he was absolutely sure this one was carcinoma. He thought these cases were too frequently called endothelioma because they were primary tumors of the lung; and perhaps this was because the best work in this line had been done by a man who believed in endothelioma with all his heart. He had been glad to hear Dr. Schultze's explanation of this tumor. Dr. Brooks said it was necessary to consider in primary tumor of the lung the embryological epithelium from which the lung is developed—air sacs—derived from a type of epithelium—endoderm—which does many curious things, as in the intestine, liver and other organs similarly derived. When one comes to the new growths, such as endothelioma, it must be remembered that tumor cells are to be dealt with, which, from an embryological standpoint, are apt to produce very variable tissues even in the normal. Dr. Brooks did not think the average primary tumor of the lung was an endothelioma, but he was not prepared to say all were not endothelioma.

Dr. Biggs asked as to the experience of others in regard to the malignancy of hypernephromata. Personally he had never seen metastasis or recurrence and he was inclined to give a favorable prognosis if the tumor were sharply outlined and not large.

Dr. Schultze said that in a case at Mt. Sinai Hospital of a pulsating tumor of the ilium diagnosed clinically as aneurism, exploratory incision revealed a mass containing blood. The microscopical diagnosis made by Dr. Mandlebaum was perithelioma. Such metastases of hypernephroma in bone were not so frequent. Struma suprarenalis (hyperplasia of adrenal cortex) he considered not so uncommon if the adrenals were systematically examined. Hypernephroma of the kidney was occasionally found, apparently having no connection with the cause of death.

Dr. Brooks said that he had had two cases last year; one in the Montefiore Home and one in the Fourth Division of Bellevue. The first was diagnosed ante mortem and showed the extremely rare metastases in the corpora cavernosa. He did not think them so uncommon if one looked out for them.

Dr. F. C. Wood said that he had seen a tumor of this type removed from a patient at St. Luke's Hospital. The tumor had occupied the upper lobe of the kidney and was of very considerable dimensions and filled with fluid blood. The inner surface of the tumor was covered with a shaggy mass of new growth. Evidently there had been a hemorrhage in the substance of the tumor with consequent destruction of the cells and the formation of the cyst. The patient had gone five years without a recurrence.

Dr. Schultze said that it seemed strange that the case with the adrenal metastasis in the inferior vena cava had not shown more marked effects of interference with circulation.

BOOK REVIEWS.

The Eye, Its Refraction and Diseases. By Edward E. Gibbons. The Macmillan Company, New York.

It may occur to some who have approached the domain of optical science through the practice of medicine that only a few of the books whose subject-matter is described by the above title, have given sufficient relative importance to that part which is devoted to refraction; the optical matter being often much curtailed or perhaps written in by some one whose name does not appear on the title page and whose interest in the book is a matter of rather secondary importance.

To say that the author of this volume has in no way underestimated the importance of the optical side of the subject is to very much understate the case. The whole book is Physiological Optics pure or applied from beginning to end. The author justly refers to the optical inadequacy of the ordinary text-book as a sufficient reason for the production of this. But the subject-matter of the book deals so little with diseases of the eye in the ordinary acceptation of the term that one wonders why the word disease appears on the cover or

the title page. This criticism is not made in a fault-finding way but merely to call attention to the fact that the diseases referred to are in general not of the inflammatory type. One can hardly find fault with the classification that places refraction anomalies and muscular insufficiencies under the head of disease, but a treatise on diseases of the eye which includes no other kind and makes no apology or explanation for the omission might be very disappointing to one who thought to read its character from its title page.

The first seventy-five pages of the book are occupied with geometrical optics, including the theory of lenses and optical systems, according to Gauss. The author has succeeded admirably in giving just about that amount of mathematical work which is found necessary and sufficient for a brief but accurate presentation of the subject. Illustrative examples are given from the eye itself, so that one acquires in the reading a familiarity with the dimensions and constants with which he is to be subsequently concerned. After this, in somewhat logical order, come those matters which should find place in a text-book introductory to Physiological Optics. At the same time the situations that must be met by the refraction-optician and oculist are presented and most of the known methods of procedure described. The book is not exhaustive but it is wise and is probably about as good as could be presented to the particular class of readers for whom it was written. The courtesy of the instrument maker has helped out a good deal with the illustrations. The letter press is good and the algebraic and geometric parts are as free from misdrawing and printers' errors as could be expected in a first edition.

TEXT-BOOK OF OPHTHALMOLOGY. By Dr. CHARLES H. MAY (Grundriss der Augenheilkunde, von Dr. Charles H. May, Chef der Augenklinik, med. Abteilung, Columbia Universität, New York. Autorisierte deutsche Ausgabe für deutsche Studierende und Aerzte. Bearbeitet von Dr. E. H. OPPENHEIMER. Verlag von August Hirschwald, Berlin.

MAY's excellent book has been given the compliment of a German translation, and in its new guise compares very favorably with any of the smaller German books that we have seen. It is not essentially different from the English edition which has been favorably commented upon in these columns. We trust it will have a successful career.

WILLIAM PEPPER, M.D., LL.D. By FRANCIS NEWTON THORPE. J. B. Lippincott Company, Philadelphia and London.

IN the general news columns of this publication, a few weeks ago, mention was made of a Life of Dr. William Pepper, late Provost of the University of Pennsylvania. Since that time a copy has come to hand and has been perused with an increasing delight. The biographer is Mr. F. N. Thorpe, concerning whose experience in this difficult form of authorship the reviewer has no knowledge. Suffice it to say that he seems to have his subject well in hand and deals fairly not only with the personality of his sketch but with the medical profession as a whole. So often are the lives of great men held in the balance of extreme prejudice or equally extreme admiration by the authorized reviewer that one must be prepared to take either praise or blame *cum grano salis* and decide for himself as to the real character of the individual, in the light of cold impartial analysis. This fact was known to no one better than to Carlyle, yet as a biographer he will never stand preeminent because of his excessive and almost unavoidable prejudices, and, strange to say, that he, too, has suffered most reprehensibly at the hands of those who, while claiming to know him so well, really understood his eccentricities so ill.

The subject in question, however, must have presented a different problem to his essayist, for if the life of any prominent man is ever intimately known to the general public, here is a case in point. Dr. Pepper was truly a man of works, but he was also a man of faith, combining well the qualities which the Biblical paragrapher laid down as indispensable. He belonged to that strictly limited class of men which Emerson was pleased to call "representative"—representative because of his greatness of heart and mightiness of mind. Standing at the head of his profession in America, he was a pioneer among those who have compelled the respect of foreigners and have made known unto all nations the breadth of vision and sincerity of purpose so characteristic of American effort in the field of medicine and surgery. But he was more than a physician, more than a mere teacher in a great school; he was also a man of affairs. His life work finished at fifty-three, it is remarkable how much he accomplished in all lines of activity during that short period of time. The list of municipal affairs with which he was prominently identified is a long one, and to name the acts of kindness performed to individuals who happened under his care would be impossible even for himself were he living. Perhaps more impossible for himself than for anyone else; for seldom were his alms done in public, and never with the hope of attracting attention, a rule which many philanthropists of to-day seem to neglect in bestowing their benefits.

This life, then, is one worthy of study by all aspiring members of the medical profession. As recorded in the volume lying before the reviewer, it is worthy of a prominent place among those books which are loved best and read most often.

HOW TO ATTRACT AND HOLD AN AUDIENCE. A Popular Treatise on the Nature, Preparation and Delivery of Public Discourse. By J. BERG ESENWEIN, A.M., Lit.D., Professor of the English Language and Literature in the Pennsylvania Military Cottage. Hinds & Noble, New York.

IT has often been said that physicians, as a rule, fail much more than other professional men, to make any proper impression when called upon to speak in public. This little book, which gives some practical hints with regard to the making of addresses, may then be of use. It is meant rather for the public speaker who makes public speaking a business, but it can well serve the purpose of the man who makes only an occasional address and in these later days, physicians are being called upon more and more to express themselves before public audiences on such popular medical questions as regard sanitary regulations and medico-educational problems. The book is especially valuable for its directions with regard to the avoidance of mannerisms that so often make the untrained speaker a source of discomfort rather than of pleasure to his audience.

DISEASES OF THE NERVOUS SYSTEM. By H. OPPENHEIM. Second American edition. Translated and edited by EDWARD E. MAYER, A.M., M.D. J. B. Lippincott Company, Philadelphia and London.

OPPENHEIM'S LEHRBUCH has represented the best of the German text-books of neurology and in its present second American dress it will find many old friends and gain, we hope, a number of new ones. The present edition represents the third German edition, published only last year. Of the general scope of the work it is not necessary to speak. In its 953 pages it tells all that

the practitioner of medicine needs to know about nervous diseases, and tells it very well. We can cordially recommend it, particularly to the inmates of sanitaria and institutions where nervous cases congregate and usually are so little studied.

Adolescence, Its Psychology and Its Relations to Physiology, Anthropology, Sociology, Sex, Crime, Religion, and Education. By G. Stanley Hall, Ph.D., LL.D., President of Clark University and Professor of Psychology and Pedagogy. Two volumes, 8vo. D. Appleton & Co., New York.

Encyclopedia of youth it might well be called. Encyclopedic it is in its information concerning the years which immediately precede and follow puberty. No period of life equals in practical import that of adolescence; yet the results of the investigation of it have been hitherto scattered and inaccessible. The teacher, the physician, the parent, the student of social problems has long asked in vain for such a work as Dr. Hall now gives us. Beginning with growth in height and weight, the normal curves are established and the significance of variations from them pointed out. The growth of parts and organs, of motor power and function are taken up with elaborate detail.

The chapters on adolescent diseases of body and mind, on juvenile faults, and on sexual development, its dangers and hygiene, are those of greatest practical medical interest. Ordinarily, the physician's militant criticism of writings on these subjects by laymen is justified. But in these chapters the present author shows himself conversant with the most advanced scientific thought, and has adopted opinions of his own of rare sagacity.

The second chapter concerns itself with the more purely psychological characteristics, such as love, attitude toward nature, social instincts, intellectual education, etc.

The book is evidently the product of years of wide reading and of acute observation. Behind it all is the philosophic purpose to establish genetic ideas of the soul which marks an extension of evolution into the psychic field.

A Manual of Clinical Diagnosis, by Means of Microscopical and Chemical Methods, for Students, Hospitals, Physicians and Practitioners. By Charles E. Simon, M.D. Fifth edition, thoroughly revised and enlarged. Lea Brothers & Co., New York and Philadelphia.

Dr. Simon's book well merits the popularity which it has achieved and which brings it to its fifth edition in eight years. Some idea of how carefully the book is brought up to date may be gathered from the additions made to the present volume. A new section, for instance, deals with the cryoscopic examination of the blood; a section had been added on paratyphoid fever and on gonococcus septicemia, as well as on bubonic plague and spotted fever. Now that animal parasites are attracting so much attention, new matter has been very seaonably added with regard to the various intestinal parasites and a special section has been devoted to trypanosomiasis. The colored plates in this edition would seem to come as near being absolute pictures in their natural colors of phases of blood work as it is possible to procure.

It is an encouraging feature of the present state of medical literature in this country to find that Dr. Simon's book is so thoroughly appreciated. The appreciation is a deserved tribute to unceasing watchfulness in keeping his work so closely in touch with real progress in practical medicine that it is a mirror of the condition of clinical diagnosis at the time of each revision and will undoubtedly, as such, prove a precious landmark for those who in the future will want to trace the introduction of various new methods into medical teaching.

BOOKS RECEIVED.

A Guide to the Clinical Examination of the Blood. By Dr. R. C. Cabot. 8vo, 550 pages. Illustrated. Wm. Wood & Co., New York.

Annual Report of the Surgeon General Public Health and Marine Hospital Service. 8vo, 572 pages. Illustrated. Washington, D. C.

The Mother's Manual. By Dr. Emelyn L. Coolidge. 12mo, 253 pages. A. S. Barnes & Co., New York.

Clinical Microscopy and Chemistry. By H. Lenhartz. Translated by H. T. Brooks. 8vo, 412 pages. Illustrated. F. A. Davis, Philadelphia.

Die Buchführung im Apothekenbetriebe. By Drs. J. Barber and V. Schestauber. 8vo, 72 pages. Illustrated. A. Hartleben, Vienna and Leipsic.

Roentgen-Ray Diagnosis and Therapy. By Dr. Carl Beck. 8vo, 460 pages. Illustrated. D. Appleton & Co., New York.

Compendium of Chemistry. By Dr. C. R. Arnold. Translated by Dr. J. A. Mandel. 8vo, 627 pages. John Wiley & Sons, New York.

Preliminary Bulletin on Insects of the Cacao. 58 pages. Illustrated. C. S. Banks, Manila.

A Manual of Materia Medica and Pharmacy. By Dr. E. S. Muir. Third edition. 8vo, 190 pages. F. A. Davis, Philadelphia.

What We Owe to Experiments on Animals. By Stephen Paget. 12mo, 72 pages. Scientific Press, London.

A Case Against Antivivisection. By Stephen Paget, 12mo, 104 pages. Scientific Press, London.

Materia Medica, Pharmacology and Therapeutics. By Dr. C. D. F. Phillips. Third edition. 8vo, 921 pages. Longmans, Green & Co., New York and Bombay.

Bericht über 137 Gallensteinlaparotomien. By Dr. Hans Kehr. 8vo, 315 pages. J. F. Lehmann, Munich.

Der Einfluss von Boden und Haus auf die Häufigkeit des Krebses. 8vo, 146 pages. J. F. Lehmann, Munich.

A Practical Treatise on Medical Diagnosis. By Dr. J. H. Musser. Fifth edition revised. 8vo, 1213 pages. Illustrated. Lea Brothers & Co., New York and Philadelphia.

Transactions of the American Climatological Association. 8vo, 264 pages. Illustrated. Philadelphia.

Le Malattie Dei Paesi Caldi. By Dr. C. Muzio. 12mo, 560 pages. Illustrated. Ulrico Hoepli, Milan.

Elettricita Medica. By Dr. A. D. Bocciardo. 12mo, 201 pages. Illustrated. Ulrico Hoepli, Milan.

La Rachitide. By Dr. P. Mancini. 12mo, 300 pages. Illustrated. Ulrico Hoepli, Milan.

Treatise on Diseases of the Skin. By Dr. H. W. Stelwagon. 8vo, 1014 pages. Illustrated. W. B. Saunders & Co., New York, Philadelphia and London.

Burdette's Hospitals and Charities. 1904. By Sir Henry Burdette. 8vo, 1029 pages. The Scientific Press, London.

Pediatrics. By D. H. E. Tuley. 12mo, 266 pages. Illustrated. Lea Brothers & Co., New York and Philadelphia.

ORIGINAL ARTICLES.

THE RELATIONS OF SURGERY TO THE RECENT ADVANCES IN THE KNOWLEDGE OF THE PANCREAS.[1] [2]

BY GEORGE WOOLSEY, M.D.,

OF NEW YORK;

SURGEON, BELLEVUE HOSPITAL, ASSOCIATE SURGEON, PRESBYTERIAN HOSPITAL; PROFESSOR OF ANATOMY AND CLINICAL SURGERY, CORNELL UNIVERSITY MEDICAL COLLEGE.

THE subject of pancreatic surgery is already so broad that I can only speak at length of certain phases of it, briefly referring to some of its other aspects. As compared with the surgery of the gall-bladder and appendix, that of the pancreas has certain natural limitations which our present knowledge of it has imposed or helped to remove.

I. On account of its physiological importance, we cannot remove the pancreas with impunity, as we can the gall-bladder and appendix. Von Mering and Minkowski showed that in dogs complete extirpation of the pancreas was invariably followed by symptoms of a fatal diabetes. Thus we cannot by a radical extirpation prevent the recurrence of a pancreatitis as occurred, for instance, in Halsted's case.

The same experimenters found that if a small portion of the gland remains, whether connected with the duct or not, there is no glycosuria until that portion atrophies. Hence, with few exceptions, tumors of the pancreas may be removed without immediate danger of diabetes, but the difficulties of the technic often contraindicate the operation. The lack of pancreatic secretion in the intestines can be supplied by administering pancreatin, but we cannot supplement the internal secretion.

The experiments of Herter in reference to the inhibition of pancreatic diabetes, after extirpation of the pancreas, by removal of the adrenals or ligation of their arteries, suggested the possibility of such removal or ligation to prevent diabetes after operations on the pancreas, or even to cure an established diabetes. But apparently the operation on the adrenals to be effective must precede the extirpation of the pancreas and even then the effect is probably not permanent.

Even incision into the pancreas has its dangers or harmful results, for not only may the hemorrhage, which is often abundant, be difficult to control, but the leakage of secretion may cause (1) a lack of peritoneal adhesions, leading to peritonitis, (2) a fat necrosis of the subperitoneal fat, (3) a chronic fistula with irritation of the surrounding skin. I have had such a case of fistula following the exploration of a carcinoma of the head of the pancreas, but have known of excision of a fragment for examination to be followed by no bad results. The trauma of an incision of the pancreas or an operation on it, radical or exploratory, may be sufficient to cause pancreatitis.

II. The topography of the pancreas, situated so deeply in the upper part of the abdomen, hinders the development of the diagnosis as well as the operative treatment of pancreatic disease. Several points in the anatomy of the pancreas have been studied or emphasized in recent years. Opie found that the duct of Santorini, though always present, could not act as an accessory outlet to the duct of Wirsung in 34 out of 100 cases, on account of the small size or absence of one or the other end. He also called attention to the relation of the pancreatic duct to the diverticulum of Vater, from which it follows that a stone of small size, impacted within the diverticulum, may completely occlude its outlet without occluding the opening of the pancreatic duct. Such an impaction of a biliary calculus prevents the outlet of bile, which is often infectious in such cases, but favors its passage into the pancreatic duct, especially if the gall-bladder is capable of contraction, thereby raising the pressure in the bile duct. The association of pancreatitis with cholelithiasis has been noted by a number of writers and it has been caused experimentally by injecting bile into the pancreatic duct. Moreover, in an autopsied human case of pancreatitis, Opie found a stone impacted in the diverticulum of Vater, causing a back flow of bile into the pancreatic duct as shown by the staining of the latter.

While this explanation of the etiology of many cases of pancreatitis does not assist the surgeon in operating when once the inflammation exists, it suggests another reason for the more general operative treatment of cholelithiasis as a prophylactic measure.

Besides the transperitoneal routes of reaching the pancreas through the gastrohepatic or gastrocolic ligaments or the mesocolon, the topography of the gland has more recently suggested the retroperitoneal route in the costovertebral angle. This is principally useful for drainage rather than for any manipulation, and is only applicable for the exposure of the head or tail of the pancreas, especially the latter, for on the right side posteriorly we have the commencement of the portal vein.

III. The severity and often rapidly fatal nature of the lesion is an impediment to successful operative treatment. Of late the opinion has been gaining ground that in acute pancreatitis it is best to operate early and not to wait for recovery from the initial collapse, but to treat the latter by infusion, etc. As I have stated elsewhere, I am heartily in favor of this course.

[2] Received for publication, February 20, 1904.

IV. As a result of the comparative rarity of acute or subacute pancreatitis, few, if any surgeons, have had a large personal experience. Although I have operated on two acute cases within ten days of one another, yet two years have gone by since operating on my third case. This limitation of personal experience lessens our skill both in diagnosis and operative treatment.

V. It is the difficulty of diagnosis which more than anything else prevents the more rapid development of the surgery of pancreatitis, as well as of other lesions of the gland. As a matter of fact the diagnosis is seldom made until the operation or autopsy reveals it. Have the recent advances in the knowledge of the pancreas added nothing to our ability to diagnose acute and subacute pancreatitis? The subjective and objective symptoms and the disturbances of function are the means that we have at our disposal. Little or nothing new can be said of the former two, while the symptoms attributable to disturbed pancreatic function are, according to the data collected by Oser, almost invariably connected with chronic lesions productive of extensive destruction of pancreatic tissue; or with interference with the passage of its secretion into the intestine.[1] When there is extensive chronic destruction of pancreatic tissue, with or without diabetes, the patient is, as a rule, beyond the help of operative measures. Glycosuria is present in only a minority of the cases. Visible fecal fat and undigested muscle fibres are most often associated with chronic obstruction of the pancreatic ducts, hence they are only of service in the diagnosis of chronic pancreatitis. The occurrence of pentose, the quantity of ethereal sulphates and the presence of the fat splitting ferment in the urine, the use of which is of recent date, are inconstant or uncertain. Only the presence of the latter, suggested by Opie, would appear to be of service in the diagnosis of acute pancreatitis, and it has not yet been sufficiently investigated. But little if any light, therefore, has been shed on the diagnosis of acute pancreatitis by recent advances in our knowledge.

I wish to call attention, however, to two points in the diagnosis of acute pancreatitis. Flexner has observed the fact[2] that in experimental pancreatitis glycosuria appears early (thirty minutes at the earliest) and disappears after a few days, even in lasting alterations of the pancreas. In the third and last case of acute pancreatitis upon which I have operated, glycosuria was present in large amount on the first day and had disappeared by the third day. In the two other cases seen for the first time on the first and third days of the attack it was not noted. It seems to me not unlikely that if we see cases of acute pancreatitis soon after the onset of the attack, transient glycosuria may be more often observed.

My limited experience coincides with that of Hahn when he says that severe acute pancreatitis, in contrast with the more subacute forms, presents quite a characteristic picture for the purposes of diagnosis, so that to make a probable diagnosis lies mostly in the realm of possibility. Its onset is sudden, with intense, colicky epigastric pain, later becoming general, severe vomiting and eructations, and distention, rigidity and tenderness, especially of the upper abdomen. There is marked collapse and the face and extremities are cold, often cyanotic and covered with a cold sweat. The pulse is small and rapid and the temperature is not high, often subnormal. Motor disturbances of the stomach and intestines, *i.e.*, vomiting and obstipation, are so commonly associated that the diagnosis of intestinal obstruction is most often made. If this symptom-complex occurs in connection with corpulence, alcoholism, gall-stones, gastroduodenal catarrh, traumatism or arteriosclerosis, conditions in which acute hemorrhagic pancreatitis is most often found, the diagnosis is made still more probable.

Though the recent advances in the knowledge of the pancreas have so far helped us very little in the diagnosis of acute pancreatitis, yet it is probable that it is and will be made more often than in the past, because we better understand the symptoms, and are more on the lookout for the condition. It is most often mistaken for acute perforative peritonitis or acute obstruction of the bowels, high up, and many times cannot be differentiated from them. Although the latter condition is not common, most cases of acute pancreatitis have been operated on with the diagnosis of intestinal obstruction.

Emphasis should be laid upon the fact that the best means of diagnosis and treatment is an early laparotomy, and that this is also the proper treatment of those conditions for which the pancreatitis may be easily mistaken, including, besides the above-named conditions, various lesions of the gall-bladder and appendix. The diagnosis is established if the exploratory incision reveals the presence of fat necrosis, which Flexner and others have shown to be due to the escape into the tissues of the fat-splitting ferment of the pancreas. If fat necrosis is not present the presence of a hemorrhagic exudate and manual examination of the pancreas may also lead to the diagnosis.

As to treatment, heretofore the expectant plan was commonly advised until the symptoms of collapse had passed off. At present I think the best surgical judgment is turning in favor of early operation. As Hahn[1] says, most severe cases die within four or five days, many indeed in the first twenty-four hours. Those that survive longer develop general peritonitis, local abscess or necrosis of the pancreas. In a very few cases the process is arrested. I do not question that, at present, statistics may show a better prognosis among those operated on for local abscess or necrosis, in what may be called the second stage, but they do not take into consideration that most

[1] Fitz: Transactions of the Congress of American Physicians and Surgeons, Vol. VI, 1903, page 37

[2] Flexner and Pearse: *University of Pennsylvania Bulletin*, August, 1901.

[1] Hahn: Deutsche med. Wochenschrift, 1901, v, p. 5.

of the cases die before reaching it, that the best means of treating the collapse is evacuation of the peritoneal exudate and an intravenous infusion, and that many cases do not develop a local abscess but a general peritonitis, as in three cases upon which I have operated. With equal reason a similar argument based on prognosis might have been (and as far as I know may have been) made against the modern operation for appendicitis in the early days of that operation.

The question of early operative treatment is associated with that of the significance of the exudate. The pancreatic secretion, from an injured pancreas, mixed with blood has a very toxic effect and in the peritoneal cavity may so affect the peritoneum as to cause death. Whether any other fatal cause, unless it be a nervous one, is at work in the rapidly fatal cases of acute hemorrhagic pancreatitis has not been determined, certainly the amount of the hemorrhage alone is not sufficient to cause death. In acute pancreatitis we have the addition of bacterial infection, for the invasion of which the local irritation of the peritoneum by the abnormal pancreatic secretion makes the way easy. Bacterial infection may be, and as a rule is, the cause of the pancreatitis. Some very acute cases of hemorrhagic pancreatitis may die before the bacterial infection has had time to affect the peritoneal exudate.

Statistics collected by von Mikulicz[1] show that drainage greatly improves the prognosis of operations for acute diseases of the pancreas. The peritoneal exudate in acute pancreatitis commonly contains bacteria of one kind or another, and the toxic and infectious nature of this exudate makes its evacuation most necessary. This is borne out by the results of early operations where merely evacuation, irrigation and drainage were employed. I have elsewhere[2] reported two cases of this kind and referred to five reported by others, all resulting successfully. Hahn[3] strongly advocates it, stating that in collapsed patients it can readily be done under cocaine anesthesia. He warns against prolonging the operation in these collapsed patients, and if fat necrosis is present, or a very large pancreas is palpated, the operator should abstain from exploration of the intestine for obstruction.

Personally I agree with Hahn, that nothing more than evacuation, irrigation and drainage should be done in these severe cases, and this can be accomplished under cocaine anesthesia. But von Mikulicz inclines to the opinion that the operation should directly include the pancreas in order to check the further development of the disease and prevent necrosis. By analogy with acute phlegmon, he reasons, *a priori*, that we should incise the pancreas to remove tension and expose the focus of infection. In support of this he appends the report of a case so treated by Dr. C. B. Porter, at the Massachusetts General Hospital. It would seem, however, that the operation on the pancreas itself, besides prolonging the whole procedure, adds the special dangers of operations upon the pancreas. Von Mikulicz[1] says "that the operation so far as it includes the organ itself, is much more dangerous than an operation upon any other abdominal organ," and he further calls attention to the greatly increased mortality in his operations for gastric cancer when the pancreas was involved. On this point we need more experience, but my own and that in the five other cases referred to points the other way. In three cases of my own, in which only evacuation, irrigation and drainage were employed, I fully expected to have to operate later for an abscess or necrosis of the pancreas, but in these and the other cases referred to as similarly treated no occasion arose for such an operation. In my third case the operation was delayed until eleven days after the commencement of the attack, and yet the pancreatitis resolved. Hahn's case was considered moribund at operation, yet recovered completely. The fact remains, though a satisfactory explanation of it may be lacking, that this simple operation both relieves the immediate condition and limits the progress of the disease.

The surgical treatment of chronic pancreatitis is an advance of recent date which we owe to the studies and work of Robson and others. Its occurrence is more common than that of the acute form and its etiology is generally a chronic catarrh of the pancreatic duct extending from a similar condition in duodenum or common bile duct.

If in addition to the pain and a tender spot an inch above the umbilicus prolonged jaundice appears, with or without a distended gall-bladder, a probable diagnosis can be made. Under anesthesia an enlargement of the head of the pancreas may be felt. Owing to a similarity in course, symptoms and signs, the diagnosis from cancer of the head of the pancreas may not be easy, even after operative exploration. Although the pain and tenderness are less marked in pancreatic cancer, whereas the jaundice is more intense and unvarying, the difficulty of distinguishing it from chronic pancreatitis has often led to postponing active interference in cases of the latter. Opie, Robson and others have called attention to the close relation between chronic pancreatitis and cholelithiasis, and even with the differences in the position and usual character of the pain and tenderness the diagnosis between the two is not always easy. In chronic pancreatitis jaundice is more constant, the gall-bladder more apt to be dilated, and there may also be disturbances of function evidenced in the urine and stools. As in the similar diagnostic predicament in acute pancreatitis, an exploratory operation is the proper course, and Robson has shown by a brilliant series of operations of considerable number that the condition may not only be relieved, but completely cured by indirect drainage through the gall-bladder, by a cholecystostomy or a chole-

1 Transactions of Congress of American Physicians and Surgeons, Vol. VI, page 58.

cystenterostomy, thereby relieving the tension, congestion and inflammation of the head of the pancreas. The mortality in Robson and Moynihan's series of cases was only about four per cent. Many cases of chronic pancreatitis have been operated on under the diagnosis of cancer of the head of the pancreas or cholelithiasis and the latter may often coexist with chronic pancreatitis, as many surgeons have experienced.

Time does not allow me to speak fully of this interesting condition, or to do more than mention a few points in connection with other surgical affections of the pancreas.

Of cysts of the pancreas, the most common lesion, as far as the number of operations is concerned, our knowledge of their etiology and pathology has advanced very materially in recent years. The fact that chronic pancreatitis is the most common cause of retention cysts adds another reason for early diagnosis of and operation for the former and its common cause or associate, cholelithiasis. Pseudo or peripancreatic cysts have been shown to constitute a large proportion of so-called pancreatic cysts. Since Gussenbauer's historic case in 1882 the most common and satisfactory operation has been incision and drainage, after fastening the cyst to the anterior abdominal wall, *i.e.*, so-called marsupialization. The mortality from this operation has been but four per cent., while two of the 23 cases of enucleation have died.[1]

Tumors of the pancreas give a less favorable outlook. Unvarying intense jaundice with a painless distended gall-bladder suggest a tumor of the head of the pancreas, which is by far the most common situation for cancer. Some 16 cases of removal of tumor of the pancreas have been reported with a mortality of 50 per cent., not so bad a result as the difficulties of the situation would lead one to expect. Franke[2] claimed to have removed the entire pancreas in a case of tumor and the operation was followed by glycosuria only from the fifth to the nineteenth day. The patient died five and a half months later. Unfortunately, these cases are left too long and are not referred to the surgeon until a palliative operation like cholecystenterostomy is the only feasible procedure.

So few cases of pancreatic calculus have been carefully observed and recorded that a typical picture of the disease cannot be given as yet. They have been met with and removed when cysts or abscess have been caused by or associated with them. One case has been recently reported by Moynihan[3] who diagnosed the condition and operated successfully upon it.

In conclusion I would like (1) to urge the more general use of Hahn's method of operating for acute pancreatitis in the early stages, by evacuation, irrigation and drainage; (2) to emphasize the fact that as several serious lesions of the pancreas may be due directly or indirectly to cholelithiasis we are provided with another indication for more frequently operating on the latter condition; (3) to suggest that as an exploratory operation is the only way of making a diagnosis in many cases of pancreatic disease, and as these, as well as the conditions they resemble, also demand prompt operative treatment, we should not hesitate to advise an early resort to it in case of any doubt. The diagnosis of an indication for exploratory incision is all that is absolutely necessary.

THE APPLICATION OF CONSERVATIVE AND RADICAL SURGERY TO CHRONIC NASAL ACCESSORY SINUS DISEASE.[1] [2]

BY R. B. CANFIELD, M.D.,
OF NEW YORK.

The subject-matter of this paper has been secured by observations upon some two hundred cases of chronic disease of the different nasal accessory sinuses, treated radically, and upon one hundred and ten cases treated conservatively. Upon a minority of these cases I have had the opportunity to operate myself. I have assisted at all the remainder and have carried out the after treatment of the great majority.

Before passing to the consideration of local treatment, I wish to add my testimony to that of those who have insisted upon the treatment of the general condition. Too many argue that, if proper local measures are taken, the general condition will speedily improve. While this is true in a great many cases, it fails in a great many. It is also true that the local condition improves much more rapidly when the general health is cared for. A hospitalized patient does not heal well, and other things being equal, that method of treatment should be chosen which the soonest discharges the patient from the house.

It is conceded that some cases of chronic empyema yield to conservative measures, while others require radical ones. It is upon the percentage of those which should belong to each class that operators differ. Jansen makes the statement that if one sinus is affected, all the sinuses on that side of the head are more or less affected, and believing that, feels compelled to adopt radical methods more often than do most other men. In my experience fully one-half of all chronic empyemas of the antrum are simple, not combined. At least in a series of forty-six cases, twenty-one were uncombined. That is, disease in the other sinuses had shown itself neither by symptom nor sign. Recognizing that empyema may lie latent without the exhibition of pus, the ethmoid and sphenoid were exploratorily opened with negative result. By far the greater number of cases can be treated successfully conservatively, and recourse to radical operation should be had infrequently. Careful and accurate diagnosis and painstaking treatment will be successful in the great majority of cases. I speak of com-

[1] Read before the Eastern Section of the American Laryngological, Rhinological and Otological Society, Fall River, Mass., Jan. 30, 1904. Presented as Thesis for membership in the American Laryngological, Rhinological and Otological Society.

[2] Received for publication March 7, 1904.

plete relief in 50 per cent. of all chronic cases and in 90 per cent. of uncombined ones.

To consider first the application of conservative treatment to chronic empyema of the antrum. There are three methods: the alveolar, that of the canine fossa, and the intranasal.

The operation through the alveolus is, in my opinion, admissible only when a diseased tooth may be considered the active etiological factor, and only in such cases can it be expected to yield good results. It is applicable to uncombined cases only, and should never be considered the operation of choice. Although according to Hajek and Killian, the antral mucous membrane has no particular predisposition to infection, still the trauma caused by forcing a drill through the alveolus may be sufficient to cause irritation enough materially to prolong the duration of the disease, even to infect a previously healthy antrum, from the germ-laden mouth secretions. Communication with the mouth is in all cases to be deprecated, and the first step in conservative treatment should be to close such an opening. The strongest argument that can be urged in favor of this method is that it affords free egress of fluid pus already in the antrum. The fact that it does not afford drainage from the most dependent part of the antral floor, is sufficient to show that it does not perfectly fulfil even this duty. Then, too, pus in the antrum is not always fluid. It many times is very tenacious and stringy, and may lie fastened so firmly to the walls or roof that it is removed with difficulty, even with the forceps. The after treatment generally employed is judicious irrigation or the dry method, followed, in order to maintain the lumen of the opening of sufficient size, by the insertion of a wick of gauge, than which there is no better medium for the conduction of infective material, unfortunately, however, in both directions. If the antrum is practically dry, that is, if there is no formation of pus in the antrum itself, the upper end of the wick is nevertheless soaked with infected secretion very soon after its insertion. Then, too, as Luc has put it, the patient is forced for a long period to take his food flavored with a sauce of iodoform and pus.

What has been said of the alveolar method may be also said of the method of operating through a small opening in the canine fassa. In addition it may be remarked that here, as no caries or diseased tissue exists, as drainage is not very good, and additional infection almost certain to take place, there is no indication for this method of operative procedure. Soon the operator is confronted by the fact that he must either insert a hard rubber obturator to maintain a permanent opening or allow the wound to close. In the one case he forces the patient to wear a foreign body in his mouth for the rest of his life, while if he adopt the other measure he may reasonably expect a recurrence. To reopen the wound is to court reinfection. It is in the pursuance of these two methods that careful control is impossible, and recurrences most frequently occur. Many times the operator, after seeing his case do well for several weeks or months, is dismayed to find not only a recurrence of symptoms, but an aggravation of the previous condition.

It is, I think, from intranasal methods that the best results from conservative surgery must be expected. To their successful use belongs not only the treatment of the sinuses affected, but of the entire nose and naso-pharynx. (This and the following statements do not refer to cases whose sole cause is an infected tooth.) Pathological conditions are always found, and it is very generally seen that permanent results are not secured until they are corrected. It is evident that a deformed middle or inferior turbinate or ethmoidal bulla may interfere with the proper drainage of a frontal, ethmoid or antrum. The fact that hypertrophic conditions are seen in almost all cases is significant. When an obstructing septal deviation exists, the empyema is found on that side toward which the septum deviates. If the posterior end of an inferior turbinate, or a mass of adenoid is seen to be markedly greater upon one side than upon the other, it is on that side that the empyema is generally to be found.

That this is not mere coincidence is, of course, granted. The question is, How far is the hypertrophy an important etiological factor in the causation of empyema, and how far does it influence its course? The hypertrophic condition, either congenital or arising from external conditions, occupation, mode of life, and so forth, particularly predisposes to influenza, diphtheria, scarlet fever, measles, and repeated head colds, which are themselves the diseases most important in the causation of empyema. It is continual sneezing, hacking and coughing that loosens the mucous membrane from the nasopharyngeal wall and predisposes to polypoid degeneration, polyps and severe infection. Nasal hypertrophy not only predisposes, but is also a direct etiological factor, and may be considered to act in one of two ways. A posterior end or a mass of adenoid may become a depot for the deposit or formation of pus, and so make a continual feeder of infective material which may find its way into any of the accessory sinuses and set up an empyema essentially chronic from the start. The condition, then, which has been so important in causation, is naturally an important agent in determining the chronicity of the disease. I can recall cases that had for months resisted treatment, some of which had gone on to radical operation with counter opening in the nose, and which continued to pour out pus for months, finally clearing up after the removal of some apparently insignificant mass of hypertrophy.

Hypertrophies act, then, as sources of infection and reinfection. They act also in another way equally important. That is, they prevent free nasal respiration, and free nasal respiration is the *sine qua non* in the successful intranasal treatment of chronic empyema. It is the failure to note this fact that compels many operators to resort unnecessarily to radical methods. It is im-

portant not only that sufficient air for breathing purposes pass through the nose, and that the patient keep his mouth closed, but that the nostrils functionate properly. According to the theory first advanced by M. Halle, of Berlin, the action of the air passing in and out through the nose is that of a chimney, drawing out the air and incidentally any secretion from the accessory sinuses through their ostia. In my opinion, this is important. In no other way can I account for the presence in the middle meatus of strings of dry tenacious pus which have made their way slowly out of the anterior accessory sinuses. It may be said that in the sinuses this pus was fluid, but dried after appearing in the nose. This may, to some extent, be true, but some of these cases, when opened radically, show just such tough strings of pus, very firmly adherent to the sinus walls. They often extend from the inner wall out through the ostium and into the nose.

Then, too, the patient, immediately after a Killian radical frontal operation, can by forced inspiration aspirate the entire serous contents of the frontal sinus backward into his throat. Nor is this aspiration confined alone to the course of the inspired air usually given in text-books. It is marked in the inferior meatus as well, as evidenced by the fact that the flow of tears can be much hastened by snuffling, and by the fact that a few grains of iodoform powder blown into the antrum soon make their appearance in the inferior meatus, if an opening be present there. To those who believe in this theory the importance of correcting any abnormalities that may interfere with free and proper nasal respiration will be evident. Drainage of the antrum by aspiration into the nose is, in my opinion, freer and as a therapeutic agent more satisfactory than drainage by any other method. This has been borne out by clinical results, for, since this theory has been evolved, cases which had previously done poorly, have, after removal of obstructing septal deviations, spurs, and so forth, made satisfactory recovery.

The first step then, in this line of surgery, is to establish free nasal respiration, and to correct any pathological condition that may exist. In attacking the antrum it is, in my mind, immaterial whether one choose the middle or the inferior meatus. Personally, I prefer the inferior. Here the bone is thicker, it is true, but there is less danger of penetrating the orbit. The inferior edge of the inferior turbinate should be removed in order to give free approach to the lateral wall of the nose. An opening should then be broken into the antrum, one-half an inch by three-quarters in size. This is easily done with an electric drill or with a mallet and chisel. A curved metal tube three-eighths of an inch in diameter is inserted into this opening, and the sinus vigorously politzerized. Very generally by this first inflation, pus is found, though in many cases, even when pus is in the antrum, it does not make its appearance at this time. The antrum should then be thoroughly irrigated, and again politzerized, irrigated and thoroughly dried. Iodoform powder may then be insufflated. By this method it is safe to say that any pus in the antrum will be secured. It is important to note that at the time of operation, or at any time during the after treatment, although the antrum may sound dry at the first politzerization, it is not wise to consider it so, for small masses of pus which are the sources of infection and which must be removed are often adherent to the walls. To overlook this fact renders the operator likely to consider the antrum healthy. This is especially true where the antrum is opened for diagnostic purposes—transillumination being negative and no positive signs of antral disease being present. A second irrigation and politzerization are necessary to dislodge such masses.

I believe in discontinuing irrigation at the earliest moment, and resorting to the dry treatment. Regeneration of the mucous membrane must thus be better assisted. This method of treating uncombined empyemas of the antrum appeals to me. The use of the electric drill is almost painless, quick and easy. It makes an opening large enough, so that the after-treatment can be carried out without discomfort and in great part by the patient himself. In favor of this method of treatment is the fact that this opening may be maintained without danger of reinfection, and that careful control is thus made possible. It should prove satisfactory in certainly not less than nine out of ten cases.

The cases which do not clear up are combined, in my experience, generally with the ethmoid. There is no doubt that the ethmoid serves as a source of infection in the great majority of obstinate combined empyemas, and in all obstinate cases should be most carefully examined. If the ethmoid is involved, removal of the anterior half of the middle turbinate exposes several of its cells. If care be taken, operating at each sitting only so far as the field is clearly visible, ethmoids of small size may be very well cleaned out through the nose. An invaluable aid is the speculum of Killian for median rhinoscopy, by which the different openings of the ethmoidal cells can be very clearly seen and the points of pus detected. Free daily use of the soft probe often detects infected cells not before suspected. Thoroughness in operating on the ethmoid is most important in determining the degree of success to be obtained. The anterior two ethmoidal cells and those extending over the orbit cannot be reached through the nose. In cases which do not yield to this much surgery, the frontal sinus is probed, catheterized or politzerized as may be possible.

In extensive ethmoidal disease involving the posterior cells, the sphenoid is at once suspected, and must be examined. The first step toward inspection of the sphenoid is the thorough removal of any septal deviation obstructing the view of the sphenoidal orifice. The opening can then in a large percentage of cases be made out. For narrow noses, where the ostium is invisible,

is suggested under cocaine and adrenalin, the use of a soft, slender silver probe, bent somewhat like a eustachian catheter, but with a more uniform gradual curve. This probe is inserted, convexity upwards, between the septum and middle turbinate, and pushed gradually upward until it rests against the cribiform plate. It is then pushed gently backward until the posterior pharyngeal wall is felt. It is now in the immediate neighborhood of the sphenoidal opening. A little manipulation very generally succeeds in passing it into the sinus. Hypertrophic turbinates do not obstruct as the probe is passed above them, and septal deviations, whether cartilaginous or bony, do not extend so high. The perpendicular plate of the ethmoid immediately below the lamina cribrosa rests almost always in the median line, so that approach to the sphenoidal orifice by this route is free.

If neither polyps or granulations can be felt, the patient may sit for ten to thirty minutes, the probe in position, and head bent forward, in the hope that any pus present may make its appearance on the probe. If this procedure is negative a slender canula following exactly the curve of the probe that has already been successful, is inserted. The sinus is catheterized and a very fair idea of its condition is secured. If it be found diseased, the entire anterior inferior wall is removed, and the sinus wiped out with cotton-carrying forceps. Great care must be taken to remove the entire wall to prevent the formation of exuberant granulations and scar tissue. By removing this wall completely the annular contraction around the orifice frequently so troublesome is largely obviated, that is, until the sinus is healed, after which it may be allowed to take place. This, of course, presupposes the correction of any septal deviation toward the affected side, and is greatly facilitated by the Killian speculum, which can be inserted almost to the posterior pharyngeal wall. The obstinate sphenoidal empyema is almost always combined with disease of the posterior ethmoid cells, so that they must always be considered together.

So far can one go along intranasal lines, and not until so much has been done, carefully and painstakingly, is one warranted in considering radical surgery. The first end to be secured is the alleviation of distressing symptoms, such as pain, headache, neuralgia, sense of head pressure and of illness. These are always greatly improved by the first evacuation of pus, which can be accomplished quite as well and with much less cost to the patient by conservative as by radical methods. It is only when there is present malignant growth, caries, cerebral symptoms, or imminent danger of fistula formation that one may proceed at once to the greater operation. One should never resort to radical surgery because the symptoms are severe, the pus foul, and the physical depression profound. It is not by any means true that the most chronic cases are always the most difficult to treat, and are those to require radical measures. One should not consider that because the patient has had a foul-smelling empyema for twenty years that it will not yield to conservative methods. Many authors have expressed surprise that antra that have discharged a most fetid pus for years should clear up completely after being irrigated a couple of times. The reason for an apparently remarkable cure is not far to seek. They belong to what Avellis calls "Eiter-Rest-" Empyema (empyema due to traces of pus), and owe their condition to the fact that after the acute inflammation has subsided the pus loses its virulence, lies stagnant in the cavity, forming slowly and being slowly discharged. The mucous membrane assumes a certain tolerance of its presence, and absorbs it with reluctance. The chief evidence of this condition is a desquamation and caseation of the antral epithelium, similar in odor and appearance to the cholesteatome of chronic suppurative middle-ear disease. As long as the natural antral orifice remains patent, the material makes its escape easily, especially at night. It is only when the orifice becomes occluded by dried pus or by some other means, that the antrum becomes filled with a semi-solid, remarkably foul, cheesy tumor that may, and sometimes does, perforate the antral wall, generally the anterior one.

When now it becomes necessary to resort to radical operation, there seems to me to be but one method to pursue. I have classed the intranasal operation, described by Dr. Curtis before this society last year, as a conservative one. When one chooses to operate radically, he feels the necessity of securing a free and comprehensive view of his operative field. This can be secured only by operating through the canine fossa. I have said that, in general, only combined empyemas require radical measures. Therefore, in operating upon the antrum, that operation should be chosen which exposes for examination and treatment not only the antrum, but also those sinuses in combination with which it is most frequently diseased, namely, the ethmoid and sphenoid. For this purpose the Kuster operation is insufficient, and the so-called Luc-Caldwell operation, or some modification of it, should be chosen. The one that appeals to me the most strongly is the one employed by Jansen, though I differ from him in some points that seem important.

The operation is as follows: (1) Careful cleansing of the teeth; (2) shallow anesthesia; (3) insertion of gauge strips between the cheek and the superior and inferior rows of teeth, to prevent hemorrhage backward into the throat.

Operation.—(1) Incision through the mucous membrane and periosteum, just above the tooth line from the first molar to the first incisor. (2) Retraction of the periosteum and resection of the entire frontal wall of the antrum. (3) Careful inspection of the antrum, its walls, mucous membrane and contents. (4) More or less thorough erasion of mucous membrane. (5) Removal of the median wall by means of forceps. (6) Curettage of the ethmoid through the area correspond-

ing to the insertion of the middle turbinate. (7) Inspection of the previously treated sphenoid and removal of any pathological contents, with resection of the entire anterior-inferior wall. (8) Formation of the mucous membrane flap and counter-opening into the nose. (9) Loose packing in the antrum, ends extending into nose. (10) Suture of the mucous membrane flap to the median end of the initial incision. (11) Complete suture of the initial incision for primary union.

In commenting upon this operation, I wish to say that a thorough and comprehensive view of the antrum, ethmoid and sphenoid is secured. The importance of leaving as much mucous membrane as possible is great. Knowledge of the pathological conditions existing in chronic antral disease, and the success of conservative methods of treatment, leads one to infer that much of the mucous membrane always removed during radical operation would, if allowed to remain, regenerate. If there is doubt in the mind of the operator concerning the viability of mucous membrane, it should not be removed. It can do no harm, and even the smallest bits shorten the duration of the after treatment. By this method of treatment, one or two anterior ethmoid cells are always found that could not be reached through the nose. In large ethmoids there still remains another anterior cell and some extending over the orbit that cannot be reached even by this method.

The mucous membrane flap may be made in two ways: An incision anteroposteriorly along the inferior edge of the attachment of the inferior turbinate is made; another along the floor of the antrum; these two are joined posteriorly. The flap thus formed is about one-half by one and a quarter inches. It is turned into the antrum and its tip sewed to the buccal mucous membrane in the line of the initial incision and near its median end. The second method is that used by Killian. It is as follows: The first incision is the same as the first incision of the other method—along the attachment of the inferior turbinate. From the anterior and the posterior ends of this incision two short ones are made vertically downwards to the floor of the antrum. The flap thus formed is turned down over the antral floor and held in position by one suture. The second flap is somewhat larger than the first, and is especially adapted to cases in which the anterior wound is to remain open, as the removal of the gauze packing through the nose is likely to loosen it. The packing in the antrum should be loose, arranged carefully, and when the primary incision is closed, should be led by two strands well into the inferior meatus. Else it is removed with difficulty, and may even require a primary anesthesia. It should remain five days. Care must be taken to smooth the edges of the bone opening to prevent the formation of exuberant granulations and possibly gangrene of the flap. The sphenoid should not be packed. If it is carefully wiped out at the time of operation, the hemorrhage from this point will generally be slight, and if it does occur, it is safer to let it bleed than to fill the sinus with gauze.

The relation of the sinus to the optic nerve and brain is so intimate, its walls so paper-thin, even containing dehiscences, that pressure upon the bleeding points of the small branches of the spheno-palatine arteries that nourish the lateral walls may cause the backing-up of blood, elevated pressure, permanent injury to the optic nerve, or even hemorrhage into the cranial cavity, as I have seen occur.

The gauze packing is removed on the fifth day, through the inferior meatus if the buccal wound was sutured at the time of operation, otherwise through the opening in the canine fossa.

The after treatment consists in a judicious use of irrigation, politzerization, and the dry method. Its duration is variable, and extends over a period of months, depending largely upon the care with which it is carried out. After the first ten days the patient, properly instructed and furnished with a suitable tube, can carry it out at home. Here again it is important to irrigate as infrequently as possible to assist the formation of new mucous membrane and scar tissue, and to prevent the formation of exuberant granulations. If these granulations form at the osteum of the sphenoid, they can be removed with a sharp spoon. In the most troublesome cases they form in the antrum, and may require even a reopening of the primary incision. Despite this fact, in all cases where it is deemed possible, the anterior wound should be closed, else the antrum becomes merely a very slowly healing depot for the reception of infective material and food. There are cases of caries, perforation and malignant growth, where the wound must remain open. In these the healing is facilitated by the early application of large Thiersch grafts, the larger the better. Packing should be discontinued early, or as soon as the grafts have taken. The granulations may be kept down by silver, and the buccal wound closed with a plug of cotton. Even after the wound has entirely healed, a roll of cotton, which can be changed at will, will generally be found to be more agreeable to the patient, and to cause less irritation to the mucous membrane than a hard rubber obturator.

Not only does an unclosed antrum serve as a receptacle for infective material, but it also often causes most unpleasant subjective symptoms, such as sensations of pain, cold, lightheadedness and occasional vertigo, which may persist.

The fact that cases of combined empyema of the antrum, ethmoid and sphenoid, which resist careful, conservative treatment, are generally those with large atypical ethmoids which are difficult, dangerous and sometimes, even by this method, impossible thoroughly to eradicate, renders doubtful the prognosis for absolute recovery, after even the most radical antral operation. These cells must be approached by another route—by an external operation generally through the frontal sinus.

Many different methods for operating upon

the frontal sinus have been advocated, but most of them have fallen into disuse. In the case of this sinus one should resort to radical methods with the greatest reluctance, and it is unfortunately here that the least can be done conservatively. In proceeding radically, one presupposes that every effort along conservative lines has been made, that neither the antrum nor the sphenoid is the cause of the continuance of the frontal disease, but that it must lie either in the frontal sinus itself or in the orbitofrontal or anterior ethmoid cells. The anterior ethmoid cells open either into the infundibulum or into the frontal sinus, and clinical experience bears out the statement that these are always infected together. The former is generally the source of the sinus disease. The operation chosen for the relief of this condition must be one to expose thoroughly both these areas. I shall consider three methods of procedure: (1) that of Hajek, the object of which is to secure drainage of the sinus; (2) that method by which the frontal sinus is to be obliterated by the formation of granulations, and by packing; (3) Killian's operation for the obliteration of the sinus without packing.

To consider the first briefly, an incision is made through the soft tissues and periosteum, passing through the eyebrow from its temporal to its median end. From the median end a second incision passes vertically upwards to the superior margin of the sinus previously determined by the Roentgen ray. An osteoplastic flap, corresponding to the anterior wall of the sinus, is then cut and turned back in the soft tissues. The entire mucous membrane is erased, bony septa removed, and the walls of the sinus smoothed off. The nasofrontal duct is enlarged as far as possible, the remaining ethmoid cells are excavated, and the sinus cleansed. A conical drainage tube is inserted into the opening between the sinus and the nose, and the wound sutured for primary union. The tube is to remain in place for at least three months, and is to be removed through the nose. It is as large as can be conveniently inserted, and sufficiently conical to hold it in position. From time to time during the after treatment it is gently drawn up and down to prevent its becoming adherent. The object in this operation is, of course, to prevent deformity and preserve the sinus, as well as to eradicate disease. In the first two the operator is generally successful. Deformity is practically absent; however, out of seven cases, Hajek reports two recurrences at eight and nine months after the operation, respectively, and while still under daily observation. These recurrences occurred unexpectedly and without symptoms. The other five cases are recent and still under treatment.

Against this method of operating there is urged in the first place that the necessity of wearing the drainage tube for three months is decidedly unpleasant. Hajek claims that epidermatization takes place readily around it, and that any granulations may easily be controlled with silver nitrate. Considerable contraction must surely take place, however, after its removal. Again, it would seem that the condition in the frontal sinus that existed before operation might again obtain. One of the chief causes of the chronicity of the disease is the deposit of small pockets of pus in the various irregular recesses of the sinus, their inspissation and subsequent formation of fibrous tissue septa. The resulting chamber-building prevents perfect drainage and tends towards recurrence. It is quite possible that with a wide communication with the nose, this reinfection and secondary chamber-formation might again occur.

The second method, that in which granulation formation from the bottom is desired and packing is to be the after-treatment, may be carried out as follows: (1) An incision through the eyebrow from its temporal to its median end, curving downward over the frontal process of the superior maxilla and cheek. (2) Frontal sinus entered through the anterior wall near the median line. (3) Formation of a narrow linear incision through the bone from the opening along the supraorbital ridge to the external boundary of the sinus. This is easily made with Doyen rongeur. (4) Enlargement of the two extremities of this incision so as to receive the jaws of the two rongeurs, by means of which the anterior frontal wall is broken off in the soft tissues to form the osteoplastic flap. The soft tissues and osteoplastic flap are then held back by a retractor which must be managed with considerable care to prevent injury and possible loss of the bone flap. (5) Removal of the floor of the sinus and inner wall of the orbit. (6) Complete erasion of the frontal mucous membrane and eradication of bony septa. (7) Curettage of the ethmoid. (8) Inspection of the sphenoid. (9) Careful cleansing of the sinus and insertion of iodoform packing. (10) Replacing of osteoplastic flap and suture of the primary incision. The center stitch and gauze to be removed on the fifth to the eighth day. Packing is then carried out through the central third of the incision, the external and internal thirds remaining undisturbed.

By this operation anterior ethmoidal and orbitofrontal cells that had escaped observation at the time of the radical antral operation are exposed. A free view of the infected sinuses is secured. Indeed, a more radical operation could scarcely be performed.

As to its after-results: First, upon the eye.—In a large percentage of cases no evil effect is noted. On the other hand, in many cases, more or less unpleasant conditions result. One symptom complained of is diplopia which follows the complete or partial loosening of the pulley of the superior oblique muscle from its bony attachment. If temporary, this diplopia lasts from seven to fourteen days; it may be permanent. Another symptom is dimness of vision, which may result from excessive lacrimation. This lacrimation is due either to ptosis and consequent faulty situation of the superior lacrimal punctum or to permanent induration at the in-

ternal angle which presses upon the lacrimal duct. Another and more serious dimness of vision results from injury to the eye itself. This may be the result of an acute iritis set up at the time of operation by pressure upon the eyeball by the retractor. This iritis may run the usual course and disappear without sequelæ, or develop into a chronic condition, evidenced by no pain, slight injection and considerable impairment of vision. Again, dimness of vision may be due to a condition which I have noticed in two cases of amblyopia following this operation. It is evidenced by a very slight injection of the nerve head and loss of its clear outline. Its fibers melt off indistinctly into the retina, especially upon the nasal side. The trouble, therefore, seemed a traumatic neuroretinitis. Vision in one case was one-thirtieth, in the other one-fifteenth. The refractive media were clear. The only abnormalities present were the ones described. In both cases the amblyopia had persisted two years.

Second, cosmetic results: Small frontal sinuses yield the best cosmetic results, for the osteoplastic flap is smaller and any displacement consequently less noted. Packing also need be continued for a shorter time. Unfortunately, accidents sometimes happen to the bone flap at the time of operation or later. It may be lost wholly or in part. During the formation of granulation tissue and subsequent retraction the upper edge may become adherent to the posterior wall of the frontal sinus and cause the lower edge to tilt forward. Both these accidents are difficult to prevent and naturally have a bad effect upon the cosmetic result. They may even require secondary or tertiary operations, which do not yield brilliant results. Another unpleasant result, which sometimes occurs, is a permanent induration in the neighborhood of the inner canthus. This can be somewhat obviated by gentle massage after the scar is firm. Again, continued packing of a wound so difficult to bandage properly and where it is desirable to expose the eye at the earliest possible moment renders infection very probable. I have seen cases most carefully treated granulate nicely from the bottom and only after a couple of months be found filled with pus. Such infection always makes an ugly scar.

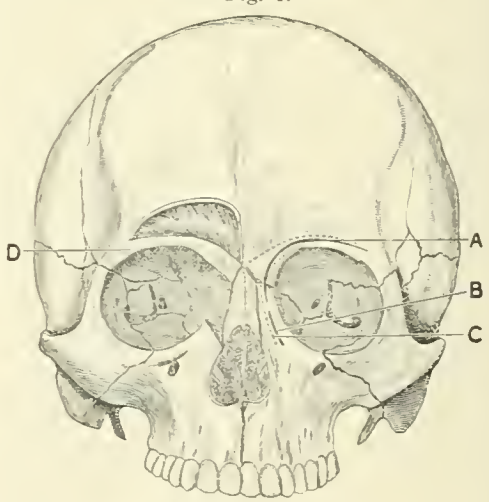
Keeping the lips of the wound separated allows the lower lip to drop down and more or less pronounced ptosis of the upper lip to result. The longer the packing, the greater the chance for reinfection, for ptosis, for induration, the greater the depression and the wider the scar. The shorter the duration of the packing, the less firm the granulation, the greater the danger of recurrence.

There is to be urged in favor of this operation that it is radical and permits as far as possible the eradication of the diseased condition. Against it is urged that it requires months of observation, packing and treatment, that the cosmetic result is doubtful, while injury to the eye is possible.

There remains to be considered the operation of Killian. Inasmuch as there exists nowhere in the literature a perfect description of its technic as it is now performed by him, I will describe it in detail.

(1) Mark the line of incision with a sharp scalpel; incision begins at the temporal end of the eyebrow and is carried through it to the root of the nose, dividing the nasal section of the musculus quadratus in the center of the frontal process of the superior maxilla. It ends in a oblique curve outward below the base of the nasal bone. (2) Periosteal Incisions.—*a*. This incision is made five to six millimeters above and parallel to the supraorbital margin. From the temporal end of the skin incision to the suture between the upper ends of the nasal bones. *b*. The lower periosteal incision follows the course of the skin incision, beginning just median to the attachment of the pulley of the superior oblique muscle. (3) Puncture the frontal sinus just above that piece of bone included between the periosteal incisions. Retract periosteum, chisel through the anterior wall of the frontal sinus, exposing but not perforating its mucous membrane. (4) Determine the size of the frontal sinus by means of a probe, moving between the bone and the mucous membrane. (5) Excise the front wall of the frontal sinus completely. (6) Erase mucous membrane. (7) Remove the floor of the sinus without injury to the supraorbital margin. While doing this, the operator stands behind the head of the patient. (8) Remove the frontal process of the superior maxilla and the remaining part of the sinus floor. Remove the frontal process without injury to the nasal mucous membrane. (9) Excavate the ethmoidal cells and sphenoid, if necessary. (10) Make the mucous membrane flap from the uninjured nasal mucous membrane. At the edge of the nasal bone perforate the nasal membrane by a pointed scalpel. By means of a probe-pointed scalpel continue the incision upward and backward one-half centimeter below the cribriform

Fig. 1.



Killian's Operation Illustrated.

A, upper periosteal incision; *B*, skin incision; *C*, lower periosteal incision; *D*, bridge of bone.

plate, then downward. This flap of the mucous membrane is turned outward and used to cover those parts of the wound facing the nasal cavity. This establishes a permanent communication between the frontal sinus and the nose. (11) Cleanse the wound with salt solution, dust with iodoform; suture the incision for primary union. (12) After-treatment. Place the patient on the healthy side; forbid him to blow his nose. He must aspirate the secreted fluid of the wound. Daily dressings. By no means flush the nasal cavity.

Procedure for radical operation of both sinuses is the same as for the operation upon one side. Begin by removing the front walls of both sinuses and remove the interfrontal septum.

COMMENTS.

The skin incision in this method is made with the greatest care and precision. It is very long and to prevent deformity and to secure perfect coaptation, attention must be paid that corresponding parts are brought into apposition. To accomplish this, it has been suggested to make little nicks at right angles to it, after its course has been marked out by the scalpel. It is not necessary to shave the eyebrow. Its presence is a valuable landmark, and it can readily be disinfected. Stitch abscesses do not occur in the orbital part of the incision, but when present are found in the dependent portion. Care is taken not to weaken the bridge of bone between the periosteal incisions by undue pressure at the time of operation, as its displacement or loss is followed by marked depression and deformity. The periosteal incisions are made with exactness. The length of the lower one has recently been changed, as it was found that loosening of the pulley of the superior oblique muscle sometimes occurred when the line of incision extended clear to the temporal end of the skin incision as it formerly did. Beginning, as it does now, median to the attachment of the pulley it has no such effect.

Attempt is made in all cases to prevent puncture of the mucous membrane of the frontal sinus as long as possible. The size of the sinus can be made out by means of the probe passed along under the bone, but outside the membrane. Unnecessary infection of the sinus cavities and wound edges is thus avoided. The anterior wall of the sinus is thoroughly removed. Any overhanging edges are taken away and left perfectly smooth as in persons with transparent skins and deep sinuses the edge is for some time plainly seen. Attention is paid to the most thorough erasion of the mucous membrane of the sinus, including the under surface of the bone flap. By standing behind the patient while removing the sinus floor the pulley of the superior oblique is avoided. Even though the bone flap is left in position the ethmoid and sphenoid are as readily accesible by this as by any other method.

The formation of the flap from the mucous membrane of the middle turbinate and the lateral wall of the nose is important as it assists materially in preventing formation of exuberant granulations and shortens the after-treatment. Atropine is instilled into the eye at the close of the operation, as a prophylactic against iritis. In this operation also especial attention must be paid to the eye. Pressure against the eye ball is to be avoided as far as possible. I think the narrower the retractor, the less the danger to the eye. The cosmetic results as far as I have been able to see have been very satisfactory. Below the bone flap there is absolutely no depression. If no stitch abscesses occur, the scar is very slight. The bridge of bone prevents loss of contour of the orbit. Removal of the entire sinus floor allows the orbital fat to push upwards so as to fill the depths of the sinus. The question arose in my mind, whether this change in the orbital pressure might not cause some anomaly in the tension of the extraocular muscles, but careful test of one case showed no heterophoria.

There is for several days after the operation more or less flat depression above the supraorbital bridge. However, by the formation of new granulations and the pushing upward of the orbital fat this is but slight and grows steadily less. If it remains noticeable it can be relieved by a subcutaneous injection of paraffin.

The statement made by Killian that he cures his patients without deforming them seems justifiable. The after-treatment is very simple. For several days the serous contents of the wound is expressed into the nose and aspirated backward by the patient. During this period of convalescence he is not allowed to blow his nose, lest he fill the wound cavity with the nucopurulent secretion of the nose or possibly cause an emphysema.

Finally the posterior surface of the soft tissues becomes adherent to the posterior frontal sinus wall. When this has taken place the patient may be considered to be more definitely healed than if his sinus were filled with a mass of granulation. After a few weeks a probe can be passed through the nose into a small cavity about the size of a hazelnut. The frontal sinus itself is completely obliterated.

CONCLUSIONS.

I have permitted myself to draw the following conclusions. Conservative methods are successful in nine out of ten uncombined cases and should always be given a thorough trial before recourse is had to radical ones. Uncombined empyemas are not uncommon. Difficulty in healing is not always in direct portion to the duration of the disease. Drainage of the antrum is most satisfactorily secured through the nose. The ethmoid is the chief cause of the chronicity of obstinate combined cases. The sphenoid is readily accessible through the nose in a large percentage of cases. It can be probed in 90 per cent. of cases by the method advised. The establishing of free nasal respiration is an important factor in securing permanent results. The radical operation should be resorted to infrequently. The best radical antrum operation

is the modified Luc-Caldwell. The best frontal operation is that of Killian. Frontal sinus operations not closed at the time of operation cause deformity. Great care must be taken of the eye at the time of the frontal operation. Accidents to the eye are: (1) Loosening the pulley of the superior oblique causing diplopia, and (2) dimness of vision due to (*a*) extraocular causes —lacrimation, conjunctivitis; (*b*) intraocular causes—iritis, neuroretinitis.

TREATMENT OF LOBAR PNEUMONIA IN THE ADULT.[1]

BY WILLIAM H. DUKEMAN, M.D.,

OF LOS ANGELES, CAL.

According to available statistics, in private practice the mortality in pneumonia ranges from five to 20 per cent., and in hospitals the mortality ranges from 20 to 50 per cent. In southern climates the death rate is higher than in the temperate climate.

After fifty years of age, the death rate is exceedingly high. The habits of the patient and the condition of the bodily health at the time of the attack are the most important factors at all ages in regard to the death rate. In individuals debilitated, either from bad habits, other diseased organs in the body, or undermined health from overwork of body or mind, the death rate is very high, while in healthy, robust individuals, the death rate is as low as from three to five per cent. In children, the mortality after the first year is small.

In summing up the mortality for all ages and under all conditions, the death rate is very high, ranking next to tuberculosis and causing more deaths than diphtheria. Like typhoid fever, the more heroic has been the treatment in the past, the higher has been the death rate. As we have no specific for either disease, the treatment resolves itself, as in typhoid, to be wholly symptomatic and supportive, and a rational line of treatment must be outlined.

By the time the physician is called to see a patient with an attack of pneumonia, the pneumococcus has invaded every avenue, and as there is at present no reliable or trustworthy antipneumococcic serum, we must confine our treatment to meet indications as presented and we must therefore be prepared to meet promptly any emergency that may arise. I, therefore, at once order to be delivered to the sick room, a 200-gallon tank of oxygen, one ounce aromatic spirits of ammonia, one ounce tincture digitalis, mustard plasters, and a cotton jacket to be made to encase the chest and put on the patient as soon as completed. The patient is placed in a large, airy room with plenty of sunlight, the bed so arranged to keep the patient out of draughts, for we require in this disease a free circulation of fresh, pure air both day and night. If the temperature is too cold, artificial heat is supplied to keep the temperature of the room at about 65° F. and a good nurse in constant attendance; no one else should be allowed in the sick chamber; quiet and rest are essential to recovery.

The existing toxemia calls for our first attention, and could we but rid the system completely of this toxemia, I am satisfied many of the serious symptoms which we may be called upon later to combat would be greatly modified or would not ensue.

To combat the toxemia, the skin and the bowels are the main avenues through which this may best be accomplished. If called to see the patient in the first stages, the skin must be acted on, not by the administration of drugs internally, but by opening up the pores by giving a good sponge bath of hot water, using plenty of soap, and then giving a hot foot bath containing mustard. This latter can best be accomplished while patient remains in bed well covered, by the placing of a small tub containing hot water and mustard under the blankets and with the knees flexed and feet in the tub, the blankets are well tucked around him. At same time I have administered a large draught of hot lemonade, which very materially aids free perspiration. The patient to remain in above position for half to one hour; when free perspiration takes place. He is to sweat for about half an hour freely, when he is to be dried and rubbed well with coarse towels to get up a good cutaneous capillary circulation. This greatly relieves the congested and dilated capillaries of the lungs and modifies, to some extent, the amount of inflammatory exudate, at same time reduces any existing high temperature. The chest is now encased in the cotton jacket and should the patient complain of any pain over seat of inflammation, a mustard plaster is placed over same and after this is removed, the chest is well oiled with camphorated oil, which is not only soothing but gives off an agreeable odor to the patient and somewhat soothes and relieves the embarrassed respiration.

The bowels are now to be acted on by the administration of two or three grains of calomel given in divided doses of half a grain every half hour, to be followed in six to eight hours by a Seidlitz powder or dose of Epsom salts. When this is accomplished we have succeeded in relieving very materially the engorged blood vessels and especially the portal and pulmonic congested circulations and any distention of the right heart, and the pulse, though frequent, will be soft and compressible, and the temperature lowered.

The action of the kidneys is best kept up by the free administration of pure water at the temperature of the room. It is a serious mistake to administer stimulating expectorants and diuretics. The least medicine given the pneumonic patient the better are his chances of recovery. To give medicines to excite too great functional activity in the already inflamed lungs or kidneys is absolutely contraindicated. The stimulating expectorants absolutely have no place in lobar pneu-

[1] Received for publication March 7, 1904.

monia. The kidneys being more or less involved in every case of pneumonia, dry cupping over the kidneys is all that is required. The teeth and mouth must be kept sweet and clean by the frequent and thorough cleansing of the same with an antiseptic solution.

To aid in the elimination of the toxemia, mild action of the bowels should be kept up, either by a daily dose of a mild saline aperient or aided by an enema of warm sterile water. The action of the skin should be maintained by the daily sponge bath of tepid water and soap.

The diet should consist of plenty of pure water at the temperature of the room, and all food should be liquid—chiefly milk. If the stomach is weak, the milk should be peptonized and be given in small quantities, not over four to six ounces at stated intervals of every three hours. Overfeeding must be avoided, as this would embarrass both respiration and circulation. If only one lobe is involved, our patient may go on to recovery without any further treatment, but if a large surface be involved or a double pneumonia exists, our skill will be taxed to the limit. The heart will be the first to need our most careful attention. Heart symptoms may develop at an early stage and the attending physician should make frequent visits to be able to recognize its earliest appearance. The nurse must be instructed and be on the alert at all times, never leaving the bedside, that she may recognize any wavering of the heart action.

The treatment of pneumonia here is the treatment of the conditions presented, not the treatment of the lungs, but the stimulation of the heart and the elimination of the toxemia. To help ward off heart weakness, I usually commence the early administration of one-sixtieth grain of strychnine hypodermically every four or six hours according to amount of lung surface involved and the condition of the circulation, and gradually and systematically increase the dose to one-thirtieth or one-twentieth grain, as circumstances demand. Strychnine acts powerfully upon the vasomotor and respiratory centers, increasing their activity, and we must not push the remedy too strongly, for strychnine is also a powerful narcotic and is also a stimulating expectorant and we may, at certain stages of the disease, increase the engorged condition of the lungs. We, therefore, should watch its action as closely as we watch the action of the wavering heart. This is why we are sometimes disappointed in the action of strychnine when it fails to strengthen the heart's action at a critical time. It is here that alcohol in the form of good rye whisky or pure brandy, in doses of one-half ounce, diluted in water, supported by five minims of tincture of digitalis, is called for and the strychnine continued in moderate doses. Should we need a more quickly acting stimulant, 30 minims of the aromatic spirits of ammonia with five to ten minims of tincture of digitalis, given in water, is called for.

I wish here to say that too heroic doses of strychnine are a mistake for the reasons above given, and if the ordinary or moderate doses do not meet the desired aim, I can justly say I have never accomplished any good results by having resorted to heroic doses.

In those cases especially where the fever runs high and there is little or no delirium, and where the heart sounds particularly the second pulmonic has lost its force, one-half ounce of whisky or brandy repeated every three hours, if the patient rests more quietly after its administration, is doing good, but should the patient become restless, it is not doing good and must be discontinued. Here is where the tincture of digitalis in small doses proves beneficial. By small doses, I mean five to ten minims in a little cinnamon water or given in conjunction with the brandy every four or six hours.

Should cyanosis appear at any time, small drinks of champagne or the aromatic spirits of ammonia in doses of 30 minims in water is called for promptly, a mustard plaster placed over the heart and the continuous inhalation of oxygen gas. For several years I have placed much reliance in the administration of oxygen. Not as it is usually given, as a last resort, but its administration throughout the course of the disease from the time of the engorgement of the inflammatory exudate to the end of resolution. The oxygen tank is by the bedside with tube and mouthpiece attached, ready for its administration. Five gallons is given every three to six hours, from the beginning of the attack, unless otherwise called for more frequently and in larger quantities. The blood must have oxygen and when the lung or lungs are engorged with the inflammatory fibrinous exudate and a vast area of the air vesicles obstructed so that the blood is very poorly oxygenized, the whole system is weakened, the toxemia is increasing, the muscles of the heart become so poisoned with the toxemia and weakened and worn out from the overwork cast upon it from an obstructed circulation that it needs something more than a whip, like stimulants, to keep a lame and crippled organ in motion. Oxygen helps to prevent, to a great extent, this condition, by keeping the blood better oxygenized, thus holding in check the increasing toxemia and thus assisting the heart to better fight its battle. At times it becomes necessary to give the oxygen continuously for hours, until the embarrassed heart and respirations show improvement and the cyanotic condition disappears. Oxygen, given throughout the course of the disease, and a plenty of it in the manner here outlined, can do no harm, but I can assure the reader that it will do much good.

I have avoided discussing the treatment of complications, as this would carry me into writing a much longer paper than is here intended.

With the treatment as above outlined and intelligently followed both by scrupulously observing changes occurring in the course of the disease and the usage of good judgment in applying the proper remedies, the rate of mortality should be much reduced.

GASTROPTOSIA.[1]

BY A. ROSE, M.D.,

OF NEW YORK.

Gastroptosia, not Gastroptosis,[2] is a subject of vast importance, as has been proved by the avalanche of literature it has caused during the last decade.

The word gastroptosia, correctly translated, means abdominal ptosis, not necessarily ptosis of the stomach alone; this latter would be stomachoptosia. The word gastroptosia is a good term, for, as far as I know the literature, all writers agree that there is, as a rule, not alone one abdominal organ descended, although one may be more displaced than the other. The word gastroptosia, for another reason, is a good term, because it includes the relaxation of the abdominal walls.

The tone, the activity of the abdominal muscles aids in fixing the abdominal organs in their physiological position. Relaxation of this apparatus forms a factor in gastroptosia, and in therapy it is the first factor we have to consider.

Enteroptosia is ptosis of the abdominal viscera in general, or, so far as literary translation is concerned, it may mean ptosis of viscera, not necessarily of the abdomen alone, certainly we may understand by this term ptosis of the bowels, but this is arbitrary. Splanchnoptosia means also ptosis of viscera, not abdominal viscera exclusively. Splanchnon can, for instance, mean the heart. I simply give facts which are worth knowing when we have science at heart.

Gastroptosia is identical with relaxation, or, which means the same, with atonia; gastroptosia is atonia gastrica. Those who have used the word atonia gastrica in the meaning of motor insufficiency of the stomach have caused much confusion.

Atonia gastrica may exist without motor insufficiency.

Myasthenia gastrica is a word without any definite meaning. Motor insufficiency is the disproportion between the capacity of the muscular forces of the stomach and the demand for labor on these forces. Such insufficiency may occur under certain circumstances in a healthy stomach, when the mass of the ingested food is too large, or the nature or condition of the ingesta unsuitable. Atony may cause insufficiency, but atony is not itself insufficiency. Atony may exist without insufficiency when the resistance at the pylorus is subnormal. Atony may be caused by insufficiency.

There exists ectasia or dilatation of the stomach, which we have to distinguish from gastroptosia, but there is no gastroptosia without dilatation. Gastroptosia depends on relaxation, and relaxation of the fibers of muscles means elongation of the fibers, therefore relaxation is, *eo ipso,* dilatation.

Glénard's whole theory of enteroptosia is based on the relaxation of the suspensory ligaments of the intestines, especially that of the transverse colon, and Stiller, the discoverer of the floating tenth rib, says that splanchnoptosia is a descent of the atonic dilated stomach, of the colon, especially of the transverse portion, the kidney, exceptionally of the liver, or the spleen; a descent which has developed mostly in tender age, in consequence of general relaxation. As a matter of course such general relaxation may be congenital or acquired.

Of practical importance is the relation between gastroptosia and gastric and nervous symptoms. We all accept now the view that many cases which formerly were classified as nervous dyspepsia are cases of gastroptosia with gastric and nervous symptoms, *ex juvantibus* any doubt can be removed.

All forms of anomalous gastric secretion may be associated with gastroptosia and as the very exact investigations of Dr. C. T. Graham Rogers, in Manhattan State Hospital, West, Ward's Island, have demonstrated, relief from anomalous secretion and motor insufficiency may promptly follow after gastroptosia has been relieved. I wish I had time to present the records Dr. Rogers had the kindness to place at my disposal showing the close relation of anomalous secretion and anomalous motor functions to gastroptosia. He confirms with scientific accuracy all I have mentioned in numerous publications.

It will simplify matters if we keep in view that the principle in the treatment of gastroptosia is relief from relaxation; first of all of abdominal relaxation, by means of support of the abdominal walls, and this can best be done in most instances by strapping in the way I have suggested.

In their enthusiasm over the study of bacterial, chemical and toxic processes many physicians of the present time have overlooked the mechanical conditions of the abdomen.

In the case of gastroptosia with gastric and nervous symptoms let us, first of all, relieve this condition of relaxation, no matter what the analysis of the contents of the stomach may show. Very often strapping of the stomach alone, without any other treatment, will restore the secretory and motor functions to a normal state. I do not mean to say that medical treatment is to be excluded in any case, but without the mechanical support all medical treatment may be in vain.

Gastroptosia may play a part in diseases of the organs of respiration and circulation.

Allow me to quote a case which I have repeatedly quoted, but which illustrates these relations to perfection.

This is a case reported by Dr. Groddeck, of Baden Baden: An elderly gentleman suffered for several years from attacks of vertigo and unconsciousness. Almost daily, sometimes hourly, and even at shorter intervals, the alarming symptoms appeared. The frequency of the pulse was

1 Received for publication March 21, 1904.

2 A feminine noun which ends in sis, xis and psis, as the second component, remains unchanged when the first component is a preposition, as, for instance, proptosis, periptosis, diagnosis; but if the first component is not a preposition, then in composition the ending is changed into sia, as eupraxia, apraxia, palingenesia, hierognosia, and also gastroptosia.

27 to 31 beats in the minute; only every second contraction of the heart caused pulsation. All the physicians who saw the case diagnosticated, quite correctly, myocarditic affection and treated him accordingly, but without success. The enormously distended belly of the patient had not been taken into consideration until Dr. Groddeck paid attention to it. The reduction of the size of the belly, although it did not cure the diseased myocardium, was followed by cessation of the attacks of vertigo and unconsciousness. The size, the weight of the belly, having been reduced, the work of the heart was materially relieved to such an extent that even the imperfect contractions were sufficient to fill the brain with the necessary quantum of blood. It is sometimes of more importance in cases of heart disease to examine the abdomen than to distinguish the fine points of the auscultatory symptoms.

I could add just as striking examples from my own practice. I could refer to my experience on seeing a patient before a medical society. Every one present studies the auscultatory symptoms, but not a single one takes notice of the most remarkably pronounced gastroptosia. They all speak of different remedies to improve the circulation, not a single one has an idea of the most important of all the remedies in the case, the support of the abdomen.

A very interesting phenomenon has been observed by Mangelsdorf. He found that every attack of migraine was accompanied by dilatation of the stomach and that repeated attacks of migraine led in the course of years to permanent change in the tonicity of the stomach, and also that there existed relations of epilepsia to gastroptosia.

Many observers of the last few years have shown that gastroptosia deserves much greater consideration than has been accorded to it.

THE TREATMENT OF TUBERCULOUS TESTICLE.[1] [2]

BY JOSEPH B. BISSELL, M.D.,

OF NEW YORK.

MUCH has been written on the small and rather limited subject of the treatment of tuberculous testicle in the past decade. Surgeons of ability and prominence on two continents have published valuable articles relating to it. The disease is probably not more prevalent than formerly, but modern methods of the treatment of tuberculosis of the lungs have drawn attention to the disease as it exists in this and other organs of the body.

Before deciding upon the treatment of this diseased condition one should consider the functions of the gland and its correlated organs, and the result which various kinds of treatment and operations suggested may have, not alone upon the organ involved, but also upon the patient and upon his future health and well being. The mere removal of one or both testicles is a comparatively simple and safe operation, but its effect upon the individual does not end with the operation and the discharge of the patient as cured. A number of cases of hopeless mental disease and some suicides have been reported as following the operation of double castration, if indeed they are not a direct result of it. A good working idea of the physiology and anatomy of the organ, together with the pathology of this infection, ought to be taken into consideration, and the physiology of the testicle as a whole must influence the surgeon in his choice of operation.

The testicle has two functions: The first, the creation of the spermatoza; and the second, and, as far as the well-being of the individual is concerned, the most important, is the formation of the internal secretion. This function resides for the most part, if not entirely, in the gland proper. The importance of this internal secretion in the metabolism of the body is well known. We all realize the psychical and physical changes produced by the removal of both testicles. The influence of their loss is shown in cases of cryptorchism, or where both testicles are lost before puberty, grave mental states and diseases having been induced by double castration even late in life.

Dr. J. B. Murphy in an elaborate and interesting article on "Tuberculosis of the Testicle," published in the *Journal of the American Medical Association*, for 1902, gives a full and simple description of the blood supply of the organ. The spermatic artery bifurcates at the border of the epididymis, and sending in its tortuous branches, suddenly becoming very much smaller in caliber, causes a sluggish and much obstructed blood supply as compared with the circulation in the testicle itself. Tubercle bacilli in the blood current, their most common way of entering the tissue, lodge more readily in the structures nourished by this slowed and impeded circulation than in the more rapid and unobstructed current in the testicle gland. Then if the epididymis, as is frequently the case, has been the seat of a preceding inflammation, gonorrhoeal or otherwise, or of a trauma, there is a nidus ready for the development of the bacilli, and tuberculous foci appear without much difficulty. This is the theory of Saltzman, who has studied the subject carefully for some years.

The most frequent channel of entrance for this bacillus into the tissues of the human body is the respiratory tract, the next most common the gastro-intestinal; then the genito-urinary mucous membrane, and lastly the skin. But whichever way it takes to get to the place of development there must be some local condition predisposing to the growth of the microbe, and the development of the disease at this point. In the testicle it is usually found to be an old or a recent epididymitis, or an injury. That this is the cause of a spot of weak resistance in the tissues which in the presence of the germ gives rise to a focus of tuberculous tissue, has been repeatedly demonstrated.

[1] Read at the New York Academy of Medicine, Genito-Urinary Section, March 16, 1904.

[2] Received for publication March 25, 1904.

In the majority of the cases recorded by Murphy he found the epididymis to contain the primary genito-urinary tuberculous infiltration, or at least the dominant focus. Such being the case the surgical indication is simple, clear and imperative. The immediate removal of this lesion would save the patient from a source of infection. The author's experience and teaching agree with that of Murphy. Unfortunately a review of the opinions of many other surgeons, who have recently written on this subject, shows a preponderance of views in favor of its being a secondary infection. Orville Horwitz, in a paper on the treatment of 96 cases, found a primary infection in some, but for the most part the disease in the epididymis was secondary to foci elsewhere. Irwin Abel in two recent papers found it to be usually secondary. E. Laval finds it secondary in most of his cases. In a paper of two years ago, Dr. H. W. Morton, of Brooklyn, apparently holds similar views. Dr. Lejar, of Paris, thinks most of the cases, if seen early enough, would show a starting point in the epididymis. The English surgeons believe for the most part that the disease is rarely primary in the epididymis.

Authors differ decidedly as to whether the disease, as far as concerns the genito-urinary tract, is an ascending or descending infection; that is, beginning in the epididymis and going upward to the vas, seminal vesicles, prostate, bladder and uretha, or whether it begins in one of these locations and reaches the epididymis in descending. Cayla in one hundred post-mortem sections, concluded that tuberculous diseases in the genito-urinary system began higher up. König in 1902, reported 31 out of 45 of his operative cases where the higher points were involved. Recent observers agree in the general view that the testicle body itself is, as a rule, involved secondarily to the epididymis. If it could be proven that genito-urinary tuberculosis in every case began in the epididymis, or even in the testicle, the surgical indications would again be direct and absolute, and if followed early enough genito-urinary tuberculosis could be cured, at least theoretically.

Another important factor must enter into our consideration of treatment of this disease, that is, the prognosis of tuberculosis as it affects other organs of the human body. It is well known that the majority of the people in this vicinity have at one time or another had greater or smaller tuberculous infections. In the autopsies in this city in deaths from all causes, it has been estimated that more than 70 per cent. of the bodies showed evidences of having suffered from pulmonary tuberculosis, many of these having scar tissue at the site of the old tuberculous inflammations. We must always take into our consideration therefore the possibility of a cure of the tuberculous process "by nature" so-called.

Treatment may be divided into constitutional or general, palliative and radical. Whichever of the latter two divisions is followed, the constitutional treatment of tuberculosis is always to be carried out. In a number of cases which were not operated upon, the patients were made comfortable for years by attention to their general health, and by means of the modern hygienic treatment for tuberculosis, carried out to the best of their ability. Nature unassisted does so much to cure tuberculosis in other organs that her efforts to prevent the growth of the bacilli in the genito-urinary tract should be helped by every means in our power before resorting to mutilations or destructive procedures. Even after we have made up our minds that it is a conservative measure to destroy or remove a certain amount of human tissues, we should still rely greatly for successful results, both immediate and ultimate, upon happily conceived and carried out general treatment, often best left to the tuberculosis specialist.

Palliative treatment is to be used where radical treatment is contraindicated. It consists principally in rest and support of the part, irrigation and cleansing of any sinus, opening and drainage of abscesses, and treatment of any symptoms which are causing temperature or distress. Mauclair's operation is on the border line between palliative and radical treatment, and in any case is useless, often harmful, and not to be recommended. It consists of excising a portion of the vascular supply of the testicle along the course of the cord. None of the various injections into the tuberculous focus recommended has been of value. Usually they increase the difficulty of proper treatment by producing a mixed infection, and finally necessitate operative interference under unfavorable local surroundings and conditions.

A palliative treatment, which seems to have great promise in it, is that held out by the use of the X-rays, radium, and the fluorescent solutions. In tuberculosis of the skin and glands the favorable results reported from this procedure promise much for the cure of tuberculosis of the testicle. My personal experience with the X-ray is disconnected and limited, and is disappointing, probably for these very reasons. Dr. W. H. Morton, of Brooklyn, who has possibly more experience with this treatment than any one else, writes me, in answer to a request of mine for information, as follows:

> I have never treated a case of the organ you refer to, but I have treated a great many cases of local tuberculous glands on the neck and side of the face near the ear and upper parts of the shoulder; five cases, at least, with complete success. Some way all my cases have been of the neck and surrounding regions. There is a steady retrogression of the grandular trouble and a final cure, depending upon the use of the X-ray, though I must say I always use quinine, esculin or fluorescin at the same time, internally, and at present believe that if one can follow up the cases carefully, that the radium will do still better work than the X-ray. My own faith in the treatment of these cases and my own success has depended upon the use of artificial fluorescence. (See *New York Medical Journal*, Feb. 13 and 20, 1904.)

The well-known fact that other glands infected with tuberculosis can be restored to normal by this means is proven, and is suggestive of

help for the same disease in the genito-urinary organs, and more particularly the testicle.

The radical treatment consists in operations of two classes. Orchiectomy or epididymectomy, either of which may be partial or complete, and either may be combined with excision of the whole or part of the vas, together with exsection of the seminal vesicles, if one wishes to go that far. Orchiectomy with removal of the vas is the most complete, especially if the seminal vesicles are removed at the same time.

Castration is easy of accomplishment, and the immediate result is good, at the worst a temporary sinus may remain, usually closing in a few weeks. But the ultimate result to the patient is not always satisfactory. The possibility of grave mental disease as a result of castration is always present. A patient deprived of both testicles, as stated earlier, is mutilated by more than the loss of his fecundating faculty. The mental impression created by such loss is not all the harm done him, serious as it is. The loss of the testicles carries with it the loss of the internal secretion, which is necessary to the health, mental and physical, of the normal male. The removal of one testicle destroys this to a certain degree. Moreover, it is not usually necessary in order to remove the tuberculous foci to take out the testicle. It has been shown by such observers as König, Cayla, Duplay, Lejars, Senn, Horwitz, Murphy and others that the lesions as a rule reach the testicle body last of all. Dr. Lejars goes so far as to save all of the body of the testicle possible, excising portions where it is infected and suturing together healthy edges of the rest of the gland, thus preserving as much of it as possible for the sake of this internal secretion.

After removing the diseased epididymis, Dr. Lejars in suspected cases does an exploratory orchidotomy, and if any nodules are seen they are excised, the cut edges brought together with buried sutures and the halves of the split testicle reunited. If it is decided to do so, after an epididymectomy or orchiectomy the vas can also be removed by following the cord to the inguinal canal, pushing back the peritoneum by a blunt dissection down to the posterior surface of the bladder, and exsecting the structure, a painstaking and somewhat tedious dissection. The cord, if diseased, is indurated and thickened, and can be easily followed.

Von Brunnen's procedure of grasping the cord after dissecting out the testicle, and pulling by main strength, thus avulsing it deeply from its attachments, seems to be unsurgical and dangerous, as likely to produce hemorrhage and possible infection. It is condemned by Murphy and by Horwitz.

There remains then for the surgical consideration the operation of epididymectomy. The removal of the diseased epididymis has these advantages. It does the least damage to the testicle functions and to the health of the patient. It removes as a rule the foci of disease. It does not destroy sexual vigor. If the disease is of the ascending variety the operation, if done early, is an absolute cure. Even after the vas and the seminal vesicles are indurated and enlarged, the vesical, vesicular and prostatic symptoms are relieved and the tenderness and induration in the cord disappears, or nearly so following this operation. This is explained by the fact that the function of the cord ceases, and therefore its activity. At the same time the infective products, derived from the tuberculous epididymitis, are cut off. In all of Horwitz's epididymectomies, even where they were double, there was no atrophy of the testicle, nor loss of sexual power. The production of the internal secretion, as it resides in the body of the gland, is not destroyed.

Excision of tubercle nodules in the gland proper interferes with its function to a much less extent than would be expected from such an operation, depending, of course, upon numbers of tuberculous foci, and the amount of tissue infiltrated. Epididymectomy to the exclusion of orchiectomy has only been popular in the last fifteen years. Scoville in 1852, and Duplay later, recommended complete extirpation of the diseased epididymis and excision of tuberculous nodes in the gland where found, as did Syme and Malgaine before them. The results, probably because of their lack of knowledge of antiseptic surgery, were not satisfactory. Of late years the success of the French and Italian surgeons again brought the operation into good repute.

The operation is a simple one, and after the first incision is merely a blunt dissection. An incision is made on the outer and posterior surface of the scrotum down to the diseased epididymis, if possible avoiding rupturing into the diseased tissues. The tumor is dissected off from below upward, and the cord tied high up. Because of oozing from the numberless little vessels impossible to tie off, and because some bacteria may get into the wound from the difficulty of satisfactory sterilization of the skin of the scrotum, it is wise to leave in a rubber tissue or silkworm drain for thirty-six to forty-eight hours. After removing the epididymis the nodules in the tunica albuginea can be excised, or one can do an explorative orchidotomy, splitting the testicle longitudinally at its posterior border and exsecting any foci, if they are present. The wound usually heals quickly on taking out the drain.

The following cases have been taken as being more or less typical of the varieties of tuberculosis of the testicle as they present themselves for treatment.

Case I.—A. L., fifty-two years old, marble cutter. January 3, 1902. Ten years ago began with hydrocele of left side. This was tapped, injected and healed. Now both epididyma are enlarged and indurated. On left side only the globus major seems to be affected; both seminal vesicles indurated and tender; right testicle is twice the normal size and tender. No frequency of micturition except slight during the day. Urine contains tubercle bacilli, as does the sputa. The urine is clear, both glasses contain a few flocculi;

heavy amount of albumin; at times the epididyma are as large as pigeon's eggs, and fluctuate at various points, but subside again. He is still under treatment. Works about his usual number of hours. No operation. General tuberculous treatment.

Case II.—F. A., fifty-three years old; sea captain. September 28, 1895. Three years ago first noticed frequency and pain in urination, lump appeared in the epididymis about same time. Hydrocele of right testicle, which has been tapped repeatedly, finally leaving a sinus connected with the globus minor. This healed in a few months after last tapping. Tubercle bacilli found in discharge from the sinus and repeatedly in the urine. Later the urinary symptoms, principally hematuria, became very pronounced until the urine seemed to be almost clear blood at every urination. He became very anemic, went to a sanitarium for treatment, and died on the operating table September, 1899. In this case the lesion began higher up. No operation upon testicle advised.

Case III.—W. D., lawyer. This patient was first seen in fall of 1887, in consultation with his physician, since dead. He had an acute urethritis and orchito-epididymitis, which followed the passage of a sound. The inflammation suppurated, and was opened and drained. Following this there remained a small sinus, which was troublesome only because of the slight seropurulent discharge. The opening would close up, a cyst would form, and have to be opened occasionally to let out the discharge until after a few years it closed and has remained so for the past eight years. He has had purulent urine for years, which, however, has not given him any further trouble. It contains tubercle bacilli, as did the discharge from the scrotal sinus, and occasionally his sputa. The testicle has almost entirely disappeared. He lives out of doors, and is very active in all his pursuits; he rides, drives and travels under the most favorable conditions; he still has purulent urine; no frequency or pain in micturition; otherwise he is in good health.

Case IV.—W. H. D., forty-nine years old. Tuberculous family history. One of his children died of tuberculosis. Has had syphilis. Called for treatment in March, 1901. Has a lump size of peanut in left globus minor; nodular vas. Noticed the lump for the last year, not tender, fluctuates slightly. Has been taking K.I. for it without result. No bladder symptoms, but urine is purulent. No tubercle bacilli found. Seminal vesicles thickened. Prostate has a few nodules in it. Takes cod-liver oil and hypophosphites. At times the lump becomes painful and tender, but subsides again. His condition remained about same at his last visit in January, 1904. General health good; appetite good; functions normal except loss of sexual vigor. Has premature ejaculation; advised against operation.

Case V.—F. D., elevator boy, March 18, 1899. Treatment, orchiectomy for tuberculosis of testicle, which healed poorly, leaving sinuses. These finally closed up after several weeks' treatment with irrigation. During this time it was noticed that the other epididymis was enlarged and tender, but he gradually improved, had no noticeable symptoms of tuberculosis in the genito-urinary tract elsewhere, and disappeared from observation. March 8, 1904, almost five years later, called to see me because he had pain in his left side due to a fall. He now has a small sinus with slight discharge connecting with the globus minor of the left epididymis. He had not noticed anything wrong there until his attention was called to it to-day. He is quite anemic, but appetite is good, and he is always at his work. His urine is clear; has no frequency of or pain in micturition. Advised epididymectomy, to which he has consented.

Case VI.—H. B., thirty-nine years old; engineer; heavy drinker; April, 1887, had several attacks of pleurisy with effusion; several attacks of bronchitis and delirium tremens; has slight consolidation of the right apex; has been under treatment for years for various injuries and diseases; dislocation of shoulder; again, later, fracture of clavicle and fractured ribs, etc., usually following an alcoholic debauch. In April, 1897, he returned to my care in his forty-ninth year for abscess and sinuses of the right scrotum. I did an epididymectomy, and he healed rapidly. He regained his health, disappeared for several years but returned to my care at Bellevue Hospital last fall with pulmonary tuberculosis of both apices. His scrotum had remained well, and he had no symptoms of bladder infection, except slightly increased frequency of urination, but with no pain; the other testicle was intact. He died of tuberculosis a few weeks later.

Case VII.—B. F., twenty-seven years old, clerk. December 3, 1897. Gives a history of hard chancre eighteen months ago followed by secondaries. Repeated attacks of urethritis; is a heavy drinker; has tuberculous family history; one sister and his mother died of it. In January, 1898, right-sided epididymitis, which apparently involves the testicle. In February, epididymis still swollen and tender. No vesical symptoms. At times the induration and tenderness of both sides are quite marked. Once during the last six years a fluctuating point in the right epididymis was opened, pus evacuated, and a sinus remained for several months. His present condition is fairly good, but both epididyma are thickened, and enlarged to several times the normal. The prostate is thickened with nodules present in it; seminal vesicles thickened. He has, however, no bladder symptoms and attends to his work, which is indoors. He has taken cod-liver oil and hypophosphites with the general hygiene for consumptives as nearly as he could for years. He has had no symptoms of syphilis and no treatment for that disease for several years. He objects to any operation, and under the circumstances, in view of his general condition, and the fact that the disease has progressed so slowly, I have not urged it. I think, however, if he began to have pain, rise of

temperature, and local suppuration, I would insist upon his deciding upon a double epididymectomy at once or not at all.

Case VIII.—George, nineteen years old. March, 1899. Was operated on for radical cure of hernia several months ago. Has a tuberculous family history; has enlarged cervical glands, one of which was removed and found to be tuberculous. For past five or six weeks his right testicle has begun to swell and he has some pain in it. Examination shows no involvment of the cord, the seminal vesicles or the prostate, but as the swelling was increasing in size, was becoming more and more painful, and the disease had evidently begun in the testicle body, the epididymis being slightly affected, if at all, it was decided in spite of his glandular infiltration to remove the organ. Wound healed up by primary union. I saw him within the past month; he has no genito-urinary symptoms, and is in good health aside from those cervical glands which, although he is working as a hospital orderly, he has still unoperated upon.

From a study of nearly 120 cases, and the suggestions derived from various writers on this subject, I would draw the following conclusions for the treatment of tuberculosis of the testicle:

Epididymectomy is the operation of election; it should be done early; it can be done with the best expectation of relief even if there are higher foci; it is not always necessary to remove the higher foci to obtain relief from their symptoms; it is indicated following a preceding castration where the remaining testicle is not involved, or if so, not very extensively.

Orchiectomy is to be performed where the testicle is markedly or alone involved (rare), or where it has broken down, and is a menace to the health of the patient, or where its removal will relieve him of a drain upon his system, and only where epididymectomy is contraindicated.

Exploratory orchidotomy following epididymectomy is indicated where single foci or a few nodules are found or suspected.

Whichever operative procedure is chosen special attention must be paid to the modern hygienic dietetic treatment for general tuberculous disease.

46 West Fifty-fifth Street.

COCAINISM.[1]

BY CHARLES J. DOUGLAS, M.D.,

OF BOSTON, MASS.;
MEDICAL DIRECTOR, DR. DOUGLAS' SANATORIUM.

The cocaine habit is a modern ailment and a most peculiar one, presenting many phases of great interest to the physician. It distinctly differs from morphinism in important respects. Cocaine is more exhilarating than morphine, but as an addiction has less tenacity of grip. Its effects are more immediately startling, but the addiction can be more readily cured.

Cocaine dilates the pupil while morphine contracts it. In many ways cocaine is a physiological antagonist to morphine, and yet they are frequently combined. In fact I have treated but few cocaine patients who did not also use morphine. This comes about through the effort of morphine habitués to abandon the use of the drug by substituting cocaine. The result is that the patient has two drug addictions instead of one, and the last state of the man is worse than the first. Another way in which this habit is acquired is by the use of nasal applications containing cocaine. I am satisfied that prescriptions of this kind are responsible for many serious results. I have treated patients who took the drug by insufflation exclusively, and who would be satisfied with no other method of administration.

It is a peculiar fact that drug habitués are almost as insistent upon the precise mode of exhibition as upon the character of the drug. Whether he takes his favorite drug by hypodermic injection, or by rectal suppositories, or via the nasal mucous membrane, or the stomach, he will strenuously insist upon the particular route he originally hit upon. Why, for instance, a man should spend unnecessary time and money on the use of rectal suppositories for systemic effect, when he could get the same results by simply swallowing a pill, is one of those psychological problems that it would be interesting to consider at length. Cocaine habitués usually employ the hypodermic needle, and as the action of the drug is very transitory, they are obliged to devote their days and nights to perpetual puncturing, if they would maintain drug action.

Cocaine produces a particularly injurious effect on the skin, causing abscesses and other sores. Consequently the industrious cocaine user soon has a large area affected. One of my patients had two arms so thoroughly covered with cicatricial tissue, as the result of this practice, that there was scarcely a point on them where a needle could be inserted. One woman, having exhausted all the available area on her arms and legs, utilized the skin across her chest. When she came to the sanatorium for treatment I found a strip four inches wide across her upper chest that presented the aspect of raw meat.

Hallucinations are often present in cocainism. These frequently relate to the skin. The patient will believe, for instance, that insects are burrowing in the cuticle, and will often make it sore in his efforts to dig out the imaginary parasite. He may also have hallucinations of hearing. Imaginary voices will continually reproach and advise him, even his most trivial acts being criticized by the "voices." One of my patients, a thoroughly educated physician, had both these symptoms to a marked degree. He believed that the parasites were not only burrowing in his skin, but infested his clothing and bed. Consequently he would take every opportunity to change his clothing, or move from one bed to another, in an effort to escape from them. On one occasion he went to an upper room in the house where he was living and, after taking off all his clothing, went down to the ground on a fire es-

[1] Received for publication March 16, 1904.

cape on the outside of the building. After he was restored to health he could not only remember all that he did, but he had a clear recollection of the reasons that impelled him. The "voices" told him that if he would take off his vermin infested clothing and go down to the ground he would there find a clean suit of clothes. By the time he reached the ground, the cool morning air against his unprotected cuticle caused an "arrest of thought," and it dawned upon him that he was standing on the lawn, clad solely in native buff, and unadorned by the arts of man. He accordingly made as rapid strides toward shelter as his unhampered limbs permitted.

Emaciation is almost a universal symptom. A recent patient of mine, who used both cocaine and morphine, came to the sanatorium weighing 102 pounds, and after the withdrawal of the drugs her weight increased to 150 pounds, which was her normal weight.

Cocaine victims are greatly distressed by insomnia. Curiously enough they employ cocaine to promote sleep, although its action is a direct antithesis to that of hypnotics. The reason for this peculiar use of the drug is that these patients are sufficiently comfortable for sleep only when under its influence. It has no hypnotic action, but relieves the distressing drug crave, and thus permits sleep to some extent.

While all drug addictions require sanatorium treatment, cocainism is one of the most readily cured. Although the results of this addiction are often appalling in the extreme, yet it is remarkable how promptly these patients usually return to a normal state, after the withdrawal of the drug under proper medical care.

THE EXTRAPERITONEAL RELATIONS OF THE APPENDIX VERMIFORMIS TO THE POSTERIOR SURFACE OF THE CECUM, WITH THE REPORT OF A FORM HITHERTO UNDESCRIBED.*†

BY C. E. BRIGGS, A.M., M.D.,

OF CLEVELAND, OHIO;

INSTRUCTOR IN SURGERY, WESTERN RESERVE UNIVERSITY; SURGEON TO THE DISPENSARY, LAKESIDE HOSPITAL.

The case to which attention is invited in this article presents a very unusual and, so far as we can find, a unique anatomical placement of the vermiform appendix.

A girl of twenty years, a patient of Dr. I. N. Oakes, of North Ridgeville, Ohio, was referred for intercurrent appendicectomy. The patient had suffered from three attacks of what appeared to be appendicular colic. The first attack was in June, 1903, and was manifest by nausea followed by pain in the right iliac fossa; the pain was not severe, and disappeared in two days; there was no fever. About a month later she had a similar attack, but even less severe. On August 20, she suffered a third attack, manifested by nausea, together with pain in the right iliac fossa, the pain being somewhat more severe than on the former occasions, and persisting for five days. On this occasion, as on the others, there was no fever, no chill and no vomiting except once immediately after taking a dose of whisky. Turpentine stupes were applied in each instance. In none of the attacks was she confined to bed, although in the last attack she felt pretty miserable. These facts in the clinical history are mentioned, as they seemed to indicate the absence of a definite inflammatory condition. Since the last attack, however, there persisted a slight degree of sensitiveness on deep pressure in the region of the appendix. The patient lived in the country a considerable distance from ready communication, which fact, together with the manifest tendency toward increasingly severe recurrence, was the occasion for operative interference.

The operation was performed at Charity Hospital, Cleveland, October 21, 1903, and presented nothing of interest aside from the anatomical condition. The cecum and appendix were readily located, there being no adhesions. The appendix emerged from the cecum at the point noted in the large majority of cases, a little internal and slightly posterior to the projection of the caput, as in the classical third type of the cecum described by Treves.[1] Curving gently upon itself in a downward and backward direction, what appeared to be the tip of the appendix seemed attached to the cecum by an adhesion about 1.5 cm. below the appendiceal base. This at first appeared to be the entire appendix, and measured 2.5 cm. There was a mesoappendix arising from the under or left layer of the mesentery of the extreme distal portion of the ileum. The mesoappendix was about 2 cm. long at the base of the appendix, and was about 4 cm. along its free border, reaching what appeared to be the adherent tip of the appendix. This free border was nowhere attached to the parietal peritoneum, so that the apparently adherent tip of the appendix could be completely surrounded by introducing the finger from the outer side underneath the appendix, beneath the mesoappendix, and out again below the free border of the mesoappendix.

The lack of any adhesions along this free border of the mesoappendix in the presence of what appeared to be an adhesion of the tip of the appendix was the first consideration that led to an understanding of the actual condition present. The end of the cecum was drawn upward, making prominent the line of reflection between the cecal and parietal peritoneum. On careful inspection it was now seen that what appeared to be the adherent tip of the appendix was merely a constriction narrowing the appendix to about one-fourth its proximal diameter. From this constriction the remainder of the appendix was seen in dim outline to lie extraperitoneally along the cecum as far as the line of peritoneal reflection mentioned, from which point it was lost to view in the retrocecal connective tissue. The extraperitoneal portion of the appendix was 1 cm. long. A short incision was made along the line of peri-

* Read at the Clinical and Pathological Section, Cleveland Academy of Medicine, March 4, 1904.

† Received for publication March 15, 1904.

toneal reflection and the retrocecal connective tissue separated along the appendix to its tip. This portion of the organ was 1 cm. long, making the entire appendix 4.5 cm. in length; the free mesenteric portion 2.5 cm., the extraperitoneal portion 1 cm., the retrocecal portion 1 cm.

The organ was readily removed. The mesenteric portion was 6 mm. in diameter, narrowing down at the constriction to a trifle over 2 mm.; beyond this point the diameter of the extraperitoneal and retrocecal portions widened out to 8 mm. The mucous membrane of the portion distal to the constriction was slightly congested, but this, together with the slight general thickening of the wall of the same portion, was the only gross evidence of inflammation. There were no adhesions. There were no foreign bodies. It is possible the distal thickening was due to muscular hypertrophy through efforts to expel mucus from this portion through the constriction. At all events the inflammation was slight and had not extended through the appendiceal wall.

That we have here a primary anatomical condition and not a condition resulting from inflammatory adhesions, there can be no reasonable doubt. An acute inflammatory condition gluing the appendix to the cecum would also have left the appendix adherent to the parietal peritoneum against which it rested posteriorly, which did not occur. An inflammatory process would undoubtedly have bound down the distal portion of the mesoappendix to the parietal surface against which it rested, but the distal border was not adherent and the finger could be freely run under it. If the extraperitoneal appearance of the middle portion of the appendix had been produced by recent adhesions, one would expect to find the remains of peritoneum on the cecal side of the appendix, but this portion of the organ was separated from the cecum only by loose connective tissue. Finally, no explanation along the line of inflammatory adhesions can possibly account for the location of the distal centimeter of the appendix lying in the retrocecal connective tissue.

The most frequent peritoneal relation of the appendix is where the entire organ lies freely in the peritoneal cavity supported by a mesoappendix extending only along the proximal half of the organ, the distal portion being without a mesentery (Quain,[2] Sappey[3]); exception is taken to this statement by more recent investigators, notably Monks and Blake,[4] the opinion prevailing that the mesentery extends further along the appendix in a much larger proportion of cases than was formerly believed. An extraperitoneal relation of all or a part of the appendix is quite rare, except as the result of an inflammatory process.

Of 577 cases mentioned by Stroud,[5] only nine were partially or wholly extraperitoneal. Bryant[6] mentions three out of 144 cases examined by H. M. Biggs. Turner, quoted by Bryant,[6] found in 105 examinations four partially, and two wholly extraperitoneal. An examination of the records of 480 autopsies, performed in the Pathological Department of Lakeside Hospital, affords a series of 440 cases in which the vermiform appendix was free from gross inflammatory conditions or operative interference. Among these 440 cases only four instances appear in which any portion of the appendix was extraperitoneal, three of which occurred in the last few autopsies. Only one of these cases sustained a relation to the posterior surface of the cecum, as is mentioned later.

There have previously been recorded several types of extraperitoneal relations of the appendix to the posterior surface of the cecum and ascending colon, all of which are so well recognized that they merit no extensive reference list.

1. As the end of the cecum is drawn forward and upward, the appendix may be seen to be extraperitoneal, lying against the posterior surface of the cecum. There is, of course, no free mesentery. It is made possible only in the case of a short or much curved appendix, or where a considerable portion of the posterior cecal surface is covered by peritoneum, and the cecoparietal peritoneal fold is high up under the upper portion of the cecum or lower end of the ascending color (Deaver[7]).

2. A second form occurs when only the proximal portion of the appendix is in extraperitoneal relation to the posterior surface of the cecum, while the distal portion to a varying degree projects freely into the peritoneal cavity, and is completely invested with the peritoneum. There may or may not be a short mesentery extending from the cecum or ileum to this free distal part of the appendix. In such cases the distal portion may be thought at first to be the entire appendix, but it is noted that the longitudinal bands of the cecum converge on the real, not the apparent base of the appendix, and on careful inspection the remainder of the organ can be seen beneath the posterior peritoneal covering of the cecum. Such an instance is mentioned by Holmes,[8] and a figure given by Huntington.[9]

3. A third variety is seen where the proximal portion of the appendix is situated extraperitoneally against the posterior surface of the cecum, while the distal portion, instead of being free as in the second variety, passes upward along the posterior aspect of the cecum and ascending colon beyond the line of the cecoparietal peritoneal reflection, and lies in the connective tissue behind the large gut, entirely out of relation to the peritoneum (Huntington[10]).

4. Another relation exists when the cecoparietal peritoneal reflection is very low down, close to the tip of the cecum, so that the entire posterior surface of the cecum is extraperitoneal, and lies in direct contact with connective tissue. An appendix in this situation lies entirely in the retrocecal connective tissue, bearing no direct relation to the peritoneum (Huntington[11]).

5. A fifth variety, a modification of the third or fourth, is observed when the tip of the appendix, for a varying length, projects beyond the cecum on either side from the retrocecal connective tissue in which is buried all the remainder of the appendix, or at least its distal portion exclu-

sive of the tip. The projecting tip is, of course, completely invested by peritoneum. Such an instance has been mentioned by Deaver,[12] and has also been recently observed by the writer.

6. Still another form is seen when the tip of the appendix lies behind the peritoneum against the posterior wall of the cecum, the proximal remainder being invested with peritoneum and supported by a mesentery that may be entirely free, or more or less adherent to the cecum. The extraperitoneal aspect may vary from what appears to be a mere adhesion, to a degree involving the entire distal half of the organ. In the first instance it resembles the case described by Treves,[13] mentioned later, in which the tip was adherent to the under surface of the mesentery of the ileum instead of the posterior cecal surface. The other extreme has been recently observed in the Pathological Department of Lakeside Hospital by Dr. D. H. Dolly, resident pathologist, the entire distal half of the appendix being extraperitoneal.

By reference to the description of the case under consideration, it will at once be seen that the situation of the appendix bears a certain relation to the third variety mentioned above. This relationship, however, is confined entirely to the distal half of the appendix, the first centimeter of which lies extraperitoneally against the under surface of the cecum, while the extreme centimeter or tip of the organ lies in the retrocecal connective tissue above the cecoparietal peritoneal fold. The proximal half of the appendix lies within the peritoneal cavity, and has an unadherent mesoappendix with a free margin, thus resembling in a degree the sixth variety described. It has been impossible for us to find, after a careful independent search, any distinct reference to a similar condition as an anatomical entity, not the result of an inflammatory process.

The nearest suggestion we can find to the peritoneal relations existing in this case is a very general statement given by Huntington,[14] in speaking of the peritoneal relations of an appendix which lies in the connective tissue behind the cecum, he says, "Even in these cases, however, the dorsal surface of the cecum and the root of the appendix retain their free serous investment." By reference to Fig. 517, described in this connection, it seems apparent that the remark applies to an appendix in which the root lies against the cecum, and "the root of the appendix" has a "free serous investment" as does the "dorsal surface of the cecum"; in other words, that the outer or free side only of the appendix is covered by peritoneum, the same layer covering the dorsal surface of the cecum.

This brings the description under the third variety mentioned above, from which reference was made to Huntington. At all events it must be observed that the text is not altogether clear, that the reference is not specific, and that no allusion is made to a free mesoappendix with an unadherent distal margin. Treves[13] mentions a case in which the appendiceal tip was adherent to the under or left layer of the mesentery of the ileum, forming a loop, but no reference is made to an extraperitoneal relation of any portion of the appendix.

It is instructive in this connection to consider certain embryological facts which may shed some light on this very unusual location of the appendix. Excellent figures illustrating these points may be found in the text of Huntington[15] or Kollman.[16] About the sixth week of the embryo the cecum develops as a bud on the posterior surface of the ascending limb of the umbilical loop. The twist toward the right of the posterior limb of this loop around the duodenocolic isthmus places the cecum in the right hypochondrium below the liver. This occurs about the fourth month, and the appendix at this time is already differentiated from the cecum by the overshadowing growth of the body of the latter. During the next three months, with but rare exceptions, the cecum gradually descends to the right iliac fossa, reaching this location about the seventh or eighth month. During this descent of the cecum with the formation of the ascending colon, the identity of the appendix is rapidly developed; a mesoappendix is doubtless present at a very early stage of this development.

In most instances as the cecum descends, the mesentery of this portion of the gut becomes adherent to the dorsal parietal peritoneum of the abdominal cavity, and identical with it, the coalescence progressing from the median line outward toward the ascending colon, and also from above downward. The peritoneal covering of the posterior part of the colon also unites with the dorsal parietal peritoneum, with which it comes in immediate contact, the two adherent layers eventually giving place to the retrocolic connective tissue. The failure of this peritoneal coalescence results in the unusual occurrence of a cecum and ascending colon, completely invested with peritoneum to a varying degree from below upward, with the presence of a longer or shorter mesentery from without inward toward the median line, according to the degreee to which the coalescence has been deficient.

The retrocecal relations of the appendix appear to bear a relation to these embryological changes. While the explanations offered for the development of these relations are of necessity largely hypothetical, still it can be said of them that they appear to be logical and sufficient. As the cecum descends, it seems that the tip of the appendix occasionally becomes adherent to the posterior abdominal wall in the line of this descent. The peritoneal relations of the appendix produced in this way would vary according as the appendiceal tip became adherent high up or low down in the cecal course. Occurring high up, the cecal descent would carry the base down, eventually rendering the appendix taut. Still further descent would cause the cecum to overhang the base of the appendix to a varying degree, so that the appendix would appear to spring from the posterior cecal wall; this condition is also accentuated by the subsequent right lateral develop-

ment of the cecum inferiorly. The descent progressing still further would eventually place the base of the appendix so far up on the posterior cecal wall that the coalescence of the cecal and parietal peritoneum with the formation of the retrocecal connective tissue would naturally reach below the base of the appendix, forming the cecoparietal peritoneal fold at this point, and thus leaving the appendix lying completely in the retrocecal connective tissue and entirely out of relation with the peritoneum. This is the condition met with in the fourth variety mentioned above.

Having these changes in mind, it is readily conceivable how some of the other relations of the appendix previously described may occur. The appendix becoming adherent lower down, or the descent of the cecum being less marked, only the distal portion of the appendix may come to lie in the retrocecal connective tissue, while the remaining proximal portion, merely being drawn snugly against the lower part of the cecum, still lies in relation to the peritoneum. The peritoneal surface of this proximal portion now lying in contact with the peritoneum of the posterior cecal wall coalesces with the latter and changes to connective tissue precisely as in the case of the cecum and parietal peritoneum, so that eventually the proximal portion is covered by peritoneum on only one side, while the distal portion lies above the cecoparietal fold in the retrocecal connective tissue. The mesoappendix also becomes adherent to the cecum, and it is sometimes thought to be traced as a thickened peritoneal surface on the cecum to the inner side of the adherent proximal portion of the appendix. In this way is explained the third form previously mentioned.

For an explanation of the case under special consideration we must naturally turn to changes produced in this same line of development, since it bears such a close and suggestive relation to the third form, the development of which we have just considered. It seems most probable that in the case reported the tip of the appendix became adherent rather late in the descent of the cecum, so that only a small portion, 1 cm., became lodged in the retrocecal connective tissue. It would seem that this condition eventuated when the cecum had nearly reached its lowest position and the appendix, instead of being drawn taut against the cecum, still had a considerable proximal portion free in the peritoneal cavity with a mesoappendix extending 2.5 cm. outward from its base. The portion of the appendix between the retrocecal tip and the mesenteric portion, a distance of 1 cm., became adherent in some way to the cecum, the adherent peritoneal surface changing to connective tissue.

That this process of adhesion of the appendix to the cecum should have stopped exactly at the point where the mesoappendix ceased, leaving the distal edge of the mesoappendix entirely free and the proximal 2.5 cm. of the appendix in the usual relation to its mesentery, is strange and very unusual, but entirely conceivable in the order of development. Had the distal edge of the mesoappendix become adherent, a fossa would have been formed extending under the free portion of the appendix and the remainder of the mesoappendix. This fossa might later have been entirely obliterated by adhesion of the mesoappendix to the cecum, the free portion of the appendix also becoming adherent, and thus produced a condition quite similar to that described under the development of the third form, though brought about in a different way.

Aside from its anatomical interest, this very unusual relation of the appendix possesses two elements of clinical interest. The unavoidable presence of a bend or kink in the appendix at the termination of its mesenteric portion has, of course, the same significance as a similar condition existing under other circumstances, the importance of which has been so admirably insisted upon by Allen.[17] The other clinical feature is the possibility of an intestinal obstruction owing to the insinuation of a nuckle of small gut under the free mesenteric portion of the appendix, beneath the mesoappendix, and out below its unadherent distal margin; such a possibility was noted by Treves[13] in the case showing a free appendiceal loop, to which reference has been made.

Although adding nothing to the present discussion, a contribution by Peronidi[18] gives an extensive bibliography on the anatomy of the cecum and appendix, containing many articles to which reference would otherwise have been made in the paper.

The Production of Prussic Acid from Albumins.—That prussic acid might possibly be formed in certain metabolic anomalies of the body would be the natural deduction. From the researches of B. H. A. PLIMMER (*Jour. of Physiol.*, May 3, 1904). By causing the oxidation of albuminous substances with Neumann's acid mixture (equal parts of strong nitric and sulphuric acids), the author succeeded in obtaining hydrocyanic acid, the amount being constant, and varying according to the form of albumin used. This substance may also be obtained by the oxidation of the products of hydrolysis of albumin.

A MODIFIED SCISSORS.

BY CHARLES C. MILLER, M.D.,
AND
J. H. LANGSTAFF, M.D.,
OF CHICAGO.

Scissors occupy a most important place among the instruments of the modern surgeon. They have been variously modified by operators to meet the peculiar requirements of surgical technic. In certain respects, we have found the scissors in common use inconvenient, and to overcome some of these inconveniences, we have adopted a modified instrument, as can be observed in the accompanying illustrations. This instrument cannot supersede the ordinary scissors for general purposes, but will prove to be useful for certain steps in the technic of not a few operations.

The instrument with the longer blades will be found invaluable in some cases in following a grooved director, and with this in view the blades should be so made as to permit this most readily. If the blade is not too wide, it can be slipped along the groove until its full length is beneath the tissues to be divided. In this way, tissues can be separated with these scissors much more rapidly, than where the ordinary pointed scissors are used. With the pointed scissors, the point alone can be

Fig. 1.

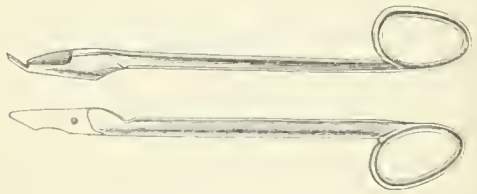

Fig. 1 illustrates the blades of the instrument separately; showing the outline of the blades.

pushed beneath the tissues to be divided, and the tissues are cut by many short snips, which is time consuming, and has the further disadvantage of making an irregular ragged cut.

Where properly made, these scissors will prove very useful in certain situations, because they permit the operator to lift up portions of tissue, before they are divided. In opening the anterior or posterior uterine cul-de-sac through the vagina, where the ordinary scissors are used, as soon as the vaginal mucosa is divided, the parts are often obscured by oozing blood. In working upward, one must either blindly snip the tissues with the ordinary scissors, or lose considerable time in having the field frequently sponged. In some cases it is very easy to enter either cul-de-sac, but in others it is not, and the procedure, is more or less blind, because of the limited space and oozing blood. While I cannot recommend the practice, many operators will open the peritoneum through the vagina, trusting to their sense of touch, to enable them to keep close to the uterine wall. This sense of touch through a long pair of scissors is uncertain, and the operator may think that he is closely following the uterine wall by the impression transmitted to his scissors, when in reality he is not. With these scissors tissues can be picked up by the small blade, and when firmly hooked beneath them, can be drawn outward, and thus are exposed to sight before they are divided. In this way no attention need be given to clearing the field of blood.

The instrument will also prove of value in doing the complete hysterectomy from above, when working our way into the vagina. The small short blade can be used to hook up a considerable

Fig. 2.

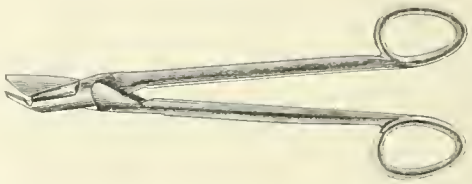

Fig. 2 illustrates the short blade which is particularly useful for removing sutures and for use in positions where space is limited.

mass of tissue, which can be quickly and certainly divided, the position of the blades making slipping less liable than in the ordinary scissors. In this operation, where time can be saved with safety by a special instrument, it is well worth while to have one at hand.

Firm strong adhesions of the viscera, can often be more safely clipped with these scissors than they can be by those ordinarily in use. Very often one will use this instrument to divide adhesions rather than to separate them with the fingers. Where an intestinal loop is firmly adherent to a solid tumor, or to the uterus, the small blade of the scissors can be pressed under the adhesion close against the uterus or tumor, and it can be more safely divided than by separation with the fingers.

In some operations, we are anxious to avoid the division of certain nerves. In cutting with the ordinary scissors or the scalpel, we must watch

Fig. 3.

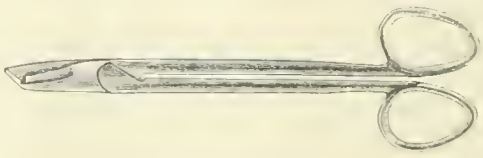

Fig. 3 will clearly illustrate the position of the blades when the instrument is closed.

very closely, lose a good deal of time sponging away slight amounts of blood, which obscure the field, and in spite of care in a certain percentage of cases, we may accidently injure the nerve. In such an operation, the tissues can be picked up rapidly by these scissors and put upon the stretch before they are divided. In this way our cellular tissue is rendered bloodless, when stretched tightly over the blade of the instrument, and the nerve

for which we are searching at once becomes visible.

These scissors were originally devised by Dr. Langstaff for the removal of sutures. In some localities considerable difficulty is experienced in picking up a silver wire or silkworm-gut suture with the ordinary scissors. In repairing the lacerated cervix, the wire or the silkworm-gut suture is superior to all others, but in some patients, particularly after repair of the perineum, it is difficult to remove them after the operation. These scissors facilitate the removal of such sutures. The small blade can be passed well under the stitch before an effort is made to divide it.

The success of perineorrhaphy often depends upon proper suturing and suture material. Catgut will always prove more or less unreliable when placed under tension. Vaginal sutures of gut to unite the perineal body are, in my mind at least, much inferior to the silkworm-gut, and I prefer the latter to the former. Where used, they should not be cut short. The long extremities of the sutures should be gathered in a bundle, and left lying in the vagina. When they have served

Fig. 4.

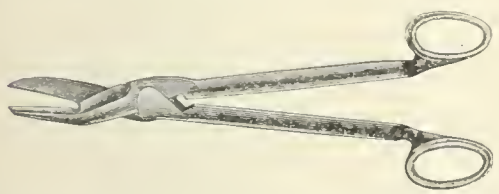

Fig. 4 is the instrument with the blade double the length of those illustrated in the former three cuts. This instrument is as a rule most useful for operative work. It may appear of doubtful advantage to burden one's instrument table with these special scissors, but their trial will, we believe, demonstrate their advantages.

their purpose, the scissors illustrated in this article will prove useful in reaching and removing them.

These scissors are of particular value in removing silver-wire sutures used in wiring the jaw, when this bone has been fractured. We always try to secure as small a scar as possible, after operations on the face. In jaw fractures, it is best to remove the silver wire, when the bone has united. The wire can be untwisted, but that will leave a spiral end, which can only be pulled through the bone with great difficulty. Without untwisting, the small blade of the scissors can be passed well under the loop, and the tissues pressed out of the way so that the wire can be cut with ease. One cannot appreciate the value of these scissors for this purpose until he has tried to cut the wire with ordinary scissors, or has attempted to draw a heavy wire through the bone, when it is more or less spirally bent, as the result of untwisting.

The instrument is more or less useful in cutting stitches in other parts, as the small blade can be slipped under the loop, and the instrument turned so that it is impossible to nip the patient accidently.

MEDICAL PROGRESS.

MEDICINE.

Lipase in the Urine.—The diagnosis of pancreatic disease, especially of the acute pancreatic form, is attended clinically with such difficulties that any accessory symptoms are welcome additions. It has long been known that in certain cases of pancreatic disease lipase, a fat-splitting ferment, appears in the urine, but the fact has hitherto not found any practical application. The test for its presence suggested by Ophüls (*Jour. Med. Research*, May, 1904) is simple enough to warrant its acceptance as a valuable practical adjuvant in diagnosis. Five c.c. of urine in two flasks are accurately neutralized with sodium hydrate solution of one-tenth normal strength; one of them is then boiled in order to destroy the lipase, and is used as a control. To each tube is now added one-fourth c.c. of ethyl butyrate, and one-tenth c.c. of toluene to prevent the development of bacteria. The flasks are incubated at 39° C. for twenty hours. The contents of each flask are now extracted with ether. If there has been considerable activity on the part of the lipase, there is a marked odor of butyric acid in the unboiled specimen. Quantitatively the acidity may be measused by titration. The lipase is probably identical with that which causes fat necrosis in the abdominal cavity.

Chronic Diphtheria.—Although the existence of this condition has been recognized for many years, there are but very few references to it in the literature. L. Neufeld (*Deutsche med. Woch.*, May 12, 1904) believes that the affection is not so rare as ordinarily supposed, but that the obscure situation of these pharyngeal ulcers renders them hard to find, or if found they are often considered as tuberculous or specific lesions. He reports a case where an ulceration of the pharynx followed an apparently simple angina. It was finally proved to be diphtheritic in character and took five months to heal. A specific diphtheritic process with the formation of a false membrane was not observed during the angina or later. Fever was only noticed during the acute stage of the angina, which lasted but two days. Behring has called attention to a group of clinical cases which he terms diphtheroids; these differ from true diphtheria in the clinical picture which they represent, but are nevertheless due to infection with the diphtheria bacillus. Neufeld thinks that his case may also be included in this group and that there are many instances where an aborted diphtheritic infection is the basis of one of these chronic processes. He also found that in many cases of atrophic rhinitis, plate cultures showed the presence, among the ozena bacillus, of several colonies of bacilli belonging to the diphtheria group. His observations are not sufficiently assuring, however, to warrant him in drawing any conclusions.

Reaction After the Use of the X-Rays.—It is claimed by H. E. Schmidt (*Deutsche med. Woch.*, May 12, 1904) that there are premonitory signs which he terms "Frühreaktionen," which come on within a few hours after an effective application of the X-rays. These are not uncommon and are erythematous in character. They must be distinguished from the dermatitis usually associated with X-rays and which is not apparent until eight to fourteen days after their application. This erythema is independent of the age of the tubes and has only been observed in isolated cases, where a particular predisposition seems to be present and where recurrence is almost

invariable. The phenomenon apparently depends on some peculiar sensibility of the circulatory system to the rays, similar to that which has been demonstrated for other influences of a psychic, toxic or thermic nature.

The Adaptation of the Pupil to the Habitual Use of Atropine.—A study in the very important field of biological adaptation has been made by W. Stefani (*Arch. Ital. de Biologie*, March 24, 1904). In studying the reaction of the pupil to the prolonged use of atropine the author noticed at first an acceleration in the appearance of the reflex and a shortening of its duration. As a second stage there is noticed a retardation in the appearance, with a diminution of intensity and duration. The first stage recalls the mode of reaction in young individuals. The adaptation is apparently connected with a more rapid circulation of the drug in the tissue elements. The quality of reaction is not changed by adaptation, which only changes the intensity of the reaction. At the end of a certain time the reaction diminishes and continues to diminish progressively until a certain point, after which it is constant. The results, according to the author, might have a general application, if they be confirmed by analogous researches on other stimuli. The various theories of immunity (phagocytic, antitoxic and humoral) must all ultimately be reduced to the adaptive capacity of the individual cell, just as the results of the author bespeak an adaptation of the cellular elements of the pupil. Other facts in biology are brought to mind. Thus, the more rapid appearance of the reaction and the shortening of the duration, correspond to an increased excitability and resistance toward the action of the drug. The repeated application of the stimulus exaggerates excitability and resistance, determines predisposition and confers immunity, refines sensibility and produces indifference. One might apply here the figure suggested by Fisher, and compare the sensitive elements to a lock and atropine to the key, adaptation being but the facilitation of the play of these elements without altering the type or the correspondence.

Medical Aspects of Decapsulation of the Kidneys for Chronic Bright's.—Only after a careful analysis and classification of the cases reported as instances of chronic Bright's disease subjected to decapsulation can we form a proper estimate of the value of this operation, in dealing with these unfortunate patients. Surgeons seem to have persuaded themselves that the disease is an unmanageable one by medical treatment, and that decapsulation is the one avenue of escape. A. R. Elliott (*N. Y. Med. Jour.*, June 4, 1904) has endeavored to classify the cases which were recently reported by Guiteras as the most complete list of operated cases in this country. It was possible by the clinical data given to fairly definitely classify 112 out of the 130 cases enumerated. Of these 29 were instances of floating kidney with albuminuria; 43 were cases of chronic interstitial nephritis, and 33 chronic parenchymatous nephritis. Of these 76 cases 36 died; 12 were unimproved; 2 rendered worse and 26 were improved. Thus 65.80 per cent. of cases failed to be improved by the operation, and of those said to be improved many of them had not passed the probationary period of six months. Certainly these statistics could not be considered as comparing favorably with the results of medical treatment upon similar cases. It is well to remember that chronic Bright's in its development constitutes a diseased condition of the entire system. It is of very gradual development and in the great majority of cases has existed for years before it is discovered. Anuria, general dropsy and even uremia in kidney disease are in many instances the result of cardiac failure, and the treatment often centers around that organ, which certainly could not be helped by this operation. Experiments demonstrate that within a period of three months and a half a new and, in most cases, a tougher fibrous capsule has taken the place of the original one. At the present time, therefore, one does not seem justified in advising an operation, the results of which are far more uncertain than those of medical treatment.

Treatment of Epidemic Cerebrospinal Meningitis by Intraspinal Antiseptic Injections.—Since the death rate from this disease during the present epidemic has ranged from 80 to 90 per cent. various methods have been resorted to in the hopes of better results. C. E. Nammack (*Med. Rec.*, June 4, 1904) reports five cases in which a ten per cent. lysol solution was injected into the spinal cord by lumbar puncture. In one case, after three injections of 15 cm. each at intervals varying from one to three days, the patient entirely recovered. The other four cases died, some of them showing temporary improvement after an injection.

Pancreas-hemoglobin Muscle Extracts in Diabetes.—Although the pancreas is known to be intimately connected in many cases, at least, with the causation of glycosuria, yet it is not at all well understood just what relation the functions of the gland has to the metabolism of sugar. It is supposed by many that an internal secretion from the pancreas converts the glucose into an assimilable carbohydrate and that when this function of the gland is lost glucose is rapidly excreted by the kidneys. A. C. Croftan (*N. Y. Med. Jour.*, May 7, 1904) by experimentation has found that by giving the pancreas gland alone to animals or human beings suffering from glycosuria, no appreciable diminution in the amount of sugar excretion is found. If, however, pancreas is placed in a sugar solution that contains hemoglobin there is a decided action in which glucose undergoes conversion. He has, furthermore, proven that by using an extract of pancreas-hemoglobin-muscle he is able to control the sugar excretion of diabetics to a considerable extent, and thus allow the patient a moderate carbohydrate diet from which he may derive the necessary nutritial qualities instead of passing the glucose off through the urine unchanged.

Increase of Pneumonia.—One of the most distressing admissions which the medical fraternity is obliged to make is its seeming inability to successfully cope with that king of diseases, pneumonia. J. H. Pleasants (*Maryland Med. Jour.*, May, 1904) shows that in 1890 the deaths from pneumonia were considerably less than those from consumption, but that there has since been a gradual increase in the number of cases and the mortality until in 1900, when pneumonia claimed almost as many victims as consumption. Even though we have found no specific by which we may treat this much-dreaded disease, yet it is not reasonable to suppose that our methods are not as efficient as they were twenty or thirty years ago. Some of the factors which he mentions as being important in determining the death rate, and especially in making the mortality seem high at the present time are: Increased density of population, climatic changes, large influx of immigration, the more accurate diagnosis, a possible increased virulence of the pneumococcus and the introduction of the influenza bacillus during the past fifteen years. Many of these factors undoubtedly diminish the resistance of the lung tissue.

Obesity.—The mode of living which is pursued by many at the present time has naturally resulted in making obesity a condition which the physician is frequently called upon to remedy. L. Williams (*Practitioner*, May, 1904) gives some valuable suggestions in regard to

the management of these cases. Obesity in its commoner forms is, of course, due to a want of balance between intake and output, either too much food is ingested or too little oxidized, but it is often very difficult to discover the nature of the want of balance. Those who have been athletic in youth are very liable to continue the habit of eating large meals, long after the necessity for that amount has ceased. Another set of persons who habitually eat too much are those deluded creatures (generally women) who imagine that they need "supporting" and proceed to eat highly nutritious foods at frequent intervals of the day. An entire separation from their ordinary environment is generally needed. Drinking large quantities of water and especially alcoholic beverages at meal time is very conducive to obesity, for it not only seems to increase the appetite, but also enables the food to pass more rapidly out of the stomach and makes it possible for the patient to eat more. Fluids should be taken a quarter or half hour before eating or after all the solids have been eaten. The importance of thorough mastication is not usually fully recognized. It is said that every mouthful should be masticated until it is both fluid and tasteless and if this is done a patient will oftentimes be satisfied with one-half the ordinary amount. A severe restriction of the proximate principles which are most readily converted into adipose tissues, such as starches, fats, sugars and alcohol, is, of course, important, but if carried too far the kidneys may be injured. To effect oxidation muscular exercise is of greatest importance, but it is frequently impossible to secure the proper amount and kind of exercise without sending the patient to some resort. The reason why as much fat is deposited in the abdomen, he believes, to be due to the fact that the abdominal muscles are not sufficiently exercised and developed. Activity of the brain must also be maintained and all tendencies to lethargy fought. He lays especial stress upon the fact that most people are too much afraid of fresh air and dress altogether too warmly, thus seriously diminishing the function of that most important organ, the skin. He discourages the prevalent use of thyroid extract as being deleterious to the heart and other organs, and urges that it be exhibited carefully and only when associated with the other details of management and hygiene.

Tetanus Treated by Intravenous Injection of Antitoxin.—It has been known for some time that the tetanus toxin exerts its influence only upon the cells of the central nervous system, particularly those of the spinal cord. Furthermore, this toxin apparently can reach the central cells only by traveling centripetally along the axis cylinder processes of the motor nerves. J. Rogers, Jr. (*Med. Rec.*, May 21, 1904) suggests that since the poison pursues this course, a much more immediate and decided effect can be obtained from the antitoxin if it is injected directly into the nerve trunks along which the toxin is traveling. Of course, if it is injected early, the subcutaneous or intravenous methods are successful, because it requires several days before the virus is able to cause symptoms arising from its action upon the cells. If symptoms have already begun, however, and these are the cases usually met with, ordinary methods are seldom efficacious. Upon a seemingly severe case in the stage of trismus and opisthotonus he exposed the lower end of the brachial plexus and injected from five to ten minims of the antitoxin in each of the median, ulnar, musculo-spiral, musculo-cutaneous and circumflex nerves. He also did a lumbar puncture, partially withdrawing the needle several times to endeavor to scratch some of the nerves of the cauda equina and thus cause a more rapid absorption. He then injected 130 minims of the antitoxin. The patient was much improved within twelve hours and more antitoxin was injected into the nerves and the cord. He made a rapid and complete recovery without showing any reaction except a rise of temperature to 102° F. on the day following the first injection.

SURGERY.

Control of Colon Hemorrhage by Left-sided Colotomy.—The control of intestinal hemorrhage is a subject which is engrossing much attention at the present time. All effort in this direction by the use of drugs has been given up by every intelligent observer. There is nothing left except mechanical treatment by surgery. Henry B. Robinson (*Lancet*, April 23, 1904) recites the history of a case in a man, sixty-six years of age, who suffered almost continuous hemorrhage from an ulcerative colitis. By good fortune, operation revealed the hemorrhage taking origin in the lower portion of the sigmoid, which part of the bowel happily escaped through the laparotomy wound. The mesentery was perforated opposite the ulcer, a glass rod slipped beneath the gut and the wound packed. The patient died in thirty-six hours. Post mortem, a well-marked ulcerated colitis was found which began at the cecum and reached to the lower end of the sigmoid. The rectum was practically healthy. The hemorrhage was entirely controlled by operation, but the work was undertaken too late to prove life saving.

Renal Reflex Pain.—Probably no organs in the body produce more acute reflex pain than the kidneys and the ureter. As a rule, although it is widely distributed over the abdomen, there is more or less segregation of the symptoms on the affected side. David Newman (*Lancet*, April 23, 1904) states that although it varies according to circumstances, it is sufficiently constant to be a very valuable guide to the surgeon in determining the nature of the involvement. The renorenal reflex pain has been described by Guyon and Thornton. Morris states that it is important to know that a stone in one kidney will sometimes excite sympathetic pain in the other, but this pain is of an aching character, differing from the usual symptom in not being spasmodic or colicky. He states that in his experience there is not a single case in which pain had been of the renorenal reflex character. The author cites three cases, which are described in full, from which he concludes that those observers who believe in the existence of this symptom are correct. He believes that an entire absence of pain may exist on the involved side. Six cases in all are discussed in this interesting article and the conclusion is, that absence of pain on the side diseased is not unusual, and is of very great clinical importance.

Intracranial Resection of the Second Division of the Fifth.—The usual mode of reaching this nerve near its origin is by following it back from its exit on the face through the floor of the orbit as nearly into the sphenomaxillary fossa as the surgeon's skill may carry him. J. Hutchinson, Jr. (*Lancet*, April 16, 1904) recommends that this disfiguring procedure should be supplanted by an intracranial operation: (1) because it is possible by this path to get nearer to the brain and make more certain the prospect of permanent cure; (2) because a depressed scar on the cheek is much more disfiguring than one hidden by the hair of the scalp. A year ago the author operated upon a ship's officer, nearly sixty years of age, who was suffering from the most intense form of facial neuralgia. As in the operation for the removal of the Gasserian ganglion, the dura and the temporosphenoidal lobe were pushed upward and inward. From this point on, however, the foramen ro-

tundum is the landmark sought rather than the foramen ovale, as in the Gasserian ganglion operation. The whole of the nerve was removed and a small drain inserted. The relief during the last twelve months has been permanent. Anesthesia is naturally well marked over the cheek, the soft palate and the lower eyelids. The patient can eat and talk with comfort, whereas before the operation both acts brought on spasmodic pain. In those cases of facial neuralgia in which the third division of the fifth is involved, this operation must ultimately become that of choice if for no other reason than because there is no interference with the muscles of mastication. The depth of the nerve trunk is 3 cm. from the temporal fossa, and the oozing in the narrow space obtainable by a pushing back of the brain is just as troublesome as in the case of Gasserian ganglion removal. In Treve's five cases pain is recurred within twelve months in two. The third patient died within six months, and in the remaining cases recurrence was observed within two and three years, respectively. Out of 22 cases of Carnochan's operation in but three was the relief stated to be permanent. This is a discouragingly low percentage of cure and bears no relation whatsoever to the results obtained in properly executed Gasserian ganglion operations.

Congenital Absence of the Patella.— The comparatively few cases of this rare condition which have been reported may be divided into two groups: (1) Includes those where there is a congenital absence of the patella, combined with other deformities of the knee-joint. This also includes those instances where during the first few years of life the patella is absent or only partially developed, but may grow more or less during later years. (2) Cases where there is a congenital and hereditary lack of both patellæ, but where the joint is otherwise perfectly normal. In the latter group is included the case reported by O. Heine (*Berl. klin. Woch.*, May 9, 1904). The patient was a man of thirty-four years, who stated that his father and sister were similarly afflicted. X-ray examination showed the complete absence of both patellæ. The condition did not appear to interfere in any way with his activities. The outer condyles and the tuberosities were markedly developed. When the man forcibly extended or flexed his knee, the quadriceps tendon slipped outward and apparently was supported by the enlarged condyle, the latter acting as a fulcrum, and in this way aiding the action of the muscle. The hypertrophied tuberosity of the tibia also seemed to take the place of the patella, by displacing the tendon further forward. From a study of the case thus far reported, it appears that the deformity is hereditary, that the knee is otherwise normal, that its function is undisturbed, and that the tuberosity of the tibia acts as an efficient substitute to the patella in the functionating of the joint.

Suprapubic Prostatectomy Under Nitrous Oxide.— The chief contraindication to the performance of prostatectomy, in many cases, has been the danger resulting from the administration of ether or chloroform. J. Wiener (*Jour. Am. Med. Ass'n*, May 14, 1904) suggests the use of nitrous oxide and reports a number of cases which he believes were the first to be done in this way. All his cases were in poor general condition and it was therefore necessary to shorten the time of operation and to avoid shock and hemorrhage. Seven patients were operated upon with good results: old age, diabetes and cystitis not proving contraindications. The operation usually took between ten and twelve minutes, some time being saved by cutting down on a distended bladder. The author believes that a previous cystoscopic examination is unnecessary and apt to do harm, often setting up an acute cystitis. He follows Lilienthal's method and employs continuous bladder drainage immediately after the operation. The gauze packing is removed at the end of twenty-four hours and a tube substituted, which remains in place usually two to three weeks. The bladder is irrigated twice daily. A sound should be passed three weeks after the operation once a week for three to four weeks longer. The only case where a perfect result was not secured was one in which this sounding was omitted and a prostatic stricture resulted.

The Prevention of Tetanus.—That it is possible to prevent tetanus if a punctured wound which has been inoculated with tetanus bacilli be treated sufficiently early by methods which are based on the knowledge of the bacteriology of the disease is the opinion advanced by D. E. Eisendrath (*Jour. Am. Med. Ass'n*, May 14, 1904). The wound is practically, in most cases, a closed one, filled with blood clots, necrotic débris and foreign bodies, and the essential thing in the treatment is to open and cleanse every part of it, preferably under general anesthesia. Prophylactic injections of tetanus antitoxin should be given to aid the organism in combating whatever toxins may have been absorbed prior to the time of operation. The blank cartridge itself does not contain the tetanus bacilli, but undoubtedly carries them from the skin while penetrating the latter. He believes that the only way to reduce the mortality is to employ the most radical procedures, with which he was successful in eight cases treated in this manner.

Antethoracic Esophagojejunostomy.—This operation is intended especially for multiple, benign stenoses of the intrathoracic segments of the esophagus, or possibly for carcinoma of the gullet in the region of the bronchus. As a substitute for the esophagus it is planned to carry a portion of the intestine out from the abdominal cavity over the bony throax and affix it to the chest. It is then proposed to expose the esophagus in the neck, to cut it through as far down as possible and also attach it to the anterior aspect of the chest wall. The intervening space between the gut and the esophagus may then be converted into a canal by means of a plastic flap. This unique procedure has been proposed by L. Wullstein (*Deut. med. Woch.*, May 12, 1904) and experiments on the dead body showed that the most suitable section of gut for the purpose was that part of the jejunum lying about 30 cm. below the plica duodenojejunalis. The jejunum may be carried up to the fourth costal cartilage without producing any great amount of tension. The flap for the plastic procedure is taken from in front of the sternum and over the right costal cartilages. It is turned so as to make a tube with the skin side within and may then be united with the gut below and the esophagus above. Animal experiments were conducted with considerable difficulty, the hair lining the tube and the trouble in nourishing the dogs interfering with the success of the procedure. Thus far no attempts have been made to apply the operation in the human subject. From his study of the method, as carried out on the cadaver, it is suggested that the operation be done in three stages, which he describes in detail. In the first, the jejunum is fixed to the anterior thoracic wall. In the second, the skin tube is formed from the plastic flap, and in the third the esophagus is isolated and united to the plastic tube. The first and second stages may be done together, but it is suggested that an interval of ten days be allowed to elapse before the third stage is completed. The same principle is also suggested for another operation which he calls retropelvic colorectostomy. In this the rectum is brought into direct communication with the descend-

ing colon outside of the pelvis in the region of the left iliac bone.

A Case of Sinus Pericranii.—Stromeyer first described this condition as a tumor under the pericranium which contains venous blood, and is in communication with the cerebral sinuses, either directly or through the medium of the venous blood, channels in the bony cranium. The lesion is a rare one and the case reported by M. LITTAUER (*Berl. klin. Woch.*, May 30, 1904) is only the tenth on record. The patient, a man of twenty-four years, received a blow on the head, which was not followed, apparently, by any serious consequences. Some two weeks later, however, after being for some time in a stooping position, the man noticed a soft swelling in the right temporal region which disappeared gradually after the erect position had been resumed. Whenever the head was bent down for any considerable period, the swelling reappeared. There were no attendant symptoms. The contents of the tumor were not cerebrospinal fluid as the presence of a hernia cerebri or a meningocele could be excluded. Blood which remained in communication with the general circulation was the only other material possible. The author believes that the injury caused a rupture of one of the veins of the diploë or of one of the emissary veins, and that the proper closure of the vessels was prevented by the dense adhesions of these structures to the surrounding tissues.

Treatment of a Third Ureter.—An interesting case is reported by HOHMEIER (*Zeitschr. f. Geb. u. Gyn.*, Vol. 51, No. 3), where there was present in a fifteen-year-old girl a third ureter, opening directly into the vagina. Earlier in life the complete hymen caused a retention of urine in the vagina from which resulted the formation of a large phosphatic calculus. This was removed, but the incontinence still continued. Operation was then decided on and the ureter implanted into the bladder through a deep perineal incision. The patient made an uneventful recovery. The absence of any scars in the perineum from obstetrical or operative sources rendered the vaginal operation very easy to perform.

Rubber Tissue and Boracic Acid in Chronic Ulcers.—Numerous methods have been suggested by which slowly healing chronic ulcerations, especially those varicose ulcers of the leg, might be more rapidly covered by healthy epithelium. W. S. SCALEY (*Med. Rec.*, June 4, 1904) reports a method which has been used with good results at the St. Luke's Hospital Dispensary. After thoroughly cleaning the surface of the ulcer it is covered by a generous quantity of boracic acid powder and then a piece of rubber tissue, large enough to extend an inch or more beyond the edges of the ulcer, is applied. This is held in place by adhesive plaster, a layer of gauze is added and the whole is firmly bound by a bandage. This dressing is allowed to remain in place from five to seven days. The advantages of this dressing are that the boracic acid acts as an antiseptic and astringent, diminishes the discharge and prevents exuberant granulations. The rubber tissue, being much smoother than gauze, prevents the roughening of the surface of the wound which is oftentimes seen to be furrowed by the latter. The rubber tissue prevents the absorption of the boracic acid by the dressing and it is also valuable for the same reason when ointments are used. The dressing may and should be left on for several days, because the tender epithelial cells are thus given a better chance to withstand manipulation. Great care should always be taken to avoid injuring the new cells.

Renal Redecapsulations.—Another step forward has been taken in the seemingly mad endeavor of surgeons to rescue unfortunate nephritics from the helpless hands of the physician. Much clinical material has now been brought forward to demonstrate the benefits to be derived from renal decapsulation and yet a careful perusal of this evidence must leave doubts in the minds of the less enthusiastic in regard to the permanent improvements. It is now admitted that decapsulation results in only temporarily removing the covering, for in a few weeks the organ is again surrounded by a capsule similar to the former one in structure and consistency. G. M. EDEBOHLS (*Med. Rec.*, May 21, 1904) reports the case of a man well till 1897 when symptoms of weakness were noticed, brick-dust sediment was found in his urine and he had one severe attack of headache and vomiting. Later urine examinations showed albumin and casts on various occasions, and in 1898 he had marked edema of feet for three months. He was subject to migraine, but apart from this and the symptoms mentioned above there were few or no symptoms of poor health during the subsequent four or five years. His urine then showed that there was some albumin and casts, and cultures from it showed the presence of *Staphylococcus albus* and the *Bacterium coli commune*. Renal decapsulation was advised and done in both kidneys. The capsule was found "slightly and unevenly thickened, but otherwise normal." He remained well for about six months after operation, when he had a severe attack of an acute infective, involving the urethra, bladder epididymis and prostate. This finally cleared up, but his anemia persisted and later uremic symptoms appeared. Renal redecapsulation was advised, but was refused until he became moribund and complete suppression of urine determined. The second operation in the hope that the latter condition might be relieved. "The new capsule was thinner and perhaps more transparent than the original capsule. There was not the slightest evidence of compression. The perirenal fat was found well vascularized, though the entire operation, including the separation of the capsule from the kidney was practically bloodless." The kidneys presented the same appearances as at the former operation. The patient died five hours later in uremic coma, but had voided considerable quantities of urine after the operation. The previous operation seems neither to have increased the vascularity of the kidney, nor to have relieved any compression.

PHYSIOLOGY.

Fermentation Experiments with the Muscle of a Mummy.—It has been shown that a positive precipitin reaction could be obtained with muscle substance taken from mummies dating back 250 to 2,000 years before Christ. E. SEHRT (*Berl. klin. Woch.*, May 9, 1904) thought it probable that in a similar manner a glycolytic action might be demonstrated. He obtained some pieces of the neck muscles from a mummy, powdered it and freed it from bacteria by aceton. The pancreatic element obtained was that of an ox, as it was impossible to secure that organ in a mummy. The experiments showed that this muscle has a marked glycolytic action, when combined with the pancreas, which is as effective as that seen with fresh muscle. The fact that a muscle, over 2,000 years old, has the power to produce reactions in a test tube, which only a comparatively short time ago were considered "vital," is not only of general scientific interest, but also serves to aid in changing present conceptions as to the nature of ferments.

Heat Regulation in Fever.—The respiratory-calorimetric investigations made on feverish children by E. BABÁK (*Pflüger's Archiv*, April 9, 1904) show that the regulatory mechanism governing temperature is subject to important disturbances in fever. The disturbance

affects the physical side of temperature regulation, namely, that which has to do with the loss of heat, more than it affects the chemical side, or that which has to do with the production of heat. Indeed, the latter may be normal. The former is detected by an abnormally diminished loss of heat. With a normal or even diminished production of heat, the temperature rises. On the other hand, there are cases in which the loss of heat is increased to a large extent and yet is not sufficient to carry off the excess of heat resulting from an accelerated production of heat. This last is proved by combined calorimetric and respiratory exchange methods. The important disturbance in the temperature-regulating mechanism in children suffering from fever is also frequently manifested in the rapid variations in the heat curve as well as the equally frequent and rapid alternations of the febrile and afebrile conditions.

Experiments on Surviving Mammalian Small Intestine.—After the removal of the mucous membrane, the spontaneous movements of the intestinal musculature continue, and are, therefore, not to be attributed to sensory stimulation of the mucous membrane, but are to be considered automatic, according to R. MAGNUS (*Pflüger's Archiv*, April 9, 1904). Likewise the removal of the submucosa and the therein contained Meissner's plexus does not affect these movements. The local peristaltic reflexes are possible also in the absence of Meissner's plexus. A simple tear at the inner border of the circular muscle does not interfere with the spontaneous movements of the circular muscle, but a similar tear at the outer edge of the latter, by virtue of which the muscle is isolated from Auerbach's plexus, causes a permanent disappearance of spontaneous movements, while the longitudinal muscle, which still remains in connection with Auerbach's plexus, preserves the normal type and rhythm of its movements. The above results show that the automatic movements of the intestinal muscle are not of myogenic origin, but depend upon centers contained in Auerbach's plexus. Possibly these results will be of value in the study of the rhythmic movements of the heart.

Blood-Platelets and Coagulation.—Many new and interesting facts of possible practical value in clinical medicine are revealed by the researches of K. BÜRKER (*Pflüger's Archiv*, March 21, 1904). A new method of obtaining the blood-platelets was devised as follows: A block of paraffin, whose upper surface has been scrupulously cleaned and smoothened, is placed in a moist chamber. A drop of blood is obtained from the tip of the finger from a wound made by the blade of a Franke's snapper, which has previously been cleaned in ether-alcohol aa, and then sterilized in the flame. The drop of blood is allowed to fall upon the smooth surface of the paraffin-plate in the moist chamber and allowed to remain in the latter for twenty to thirty minutes. The blood does not coagulate, provided that drying or contact with foreign bodies does not take place. The formed elements of the blood begin to separate, the heavy red and white corpuscles falling to the bottom of the drop, and the blood-platelets, being light, rise to the top. At the end of twenty to thirty minutes the top of the drop is touched with the surface of a cover-glass, which is then placed on a slide. Under the microscope are now found many blood-platelets and no red or colorless corpuscles. The author found that the blood-platelets are independent elements, and are not formed from red or colorless corpuscles. The author devised a new method for the determination of the coagulation-time of the blood, by which only a drop of blood is used, and in which the error never amounts to more than half a minute. The temperature influences coagulation-time. Thus at 13.7° C. the time is 18½ minutes; at 24.2° C. it is 6½ minutes; at 39.8° C. it is 2¾ minutes. A regular curve indicating the effect of temperature may be constructed. The effect of the temperature is so great and precise that, knowing the coagulation-time the temperature may be calculated. Independent of the variations in coagulation-time, corresponding to the varying temperatures of the day, there is a physiological variation in the former as follows: the minimum is reached during the early afternoon hours. For different individuals coagulation-time is fairly constant. Coagulation is closely connected with the destruction of blood-platelets. The amount of fibrin formed depends upon the number of destroyed blood-platelets. Moreover, all these factors that affect coagulation, such as temperature, wall of blood-vessel and chemical substances, act in a corresponding way upon the blood-platelets. If the latter are destroyed, then coagulation occurs; otherwise not. Thus, an extract obtained from the leech is capable of inhibiting coagulation. This substance, which is an albumin or an albuminous derivative, likewise inhibits the destruction of the blood-platelets. Certain quantitative and gravimetric observations indicate that the blood-fibrin is derived from the blood-platelets.

Physiology of the Thyroid.—In looking over the literature upon the thyroid gland, K. KISHI (*Virchow's Archiv*, Vol. 176, No. 2) discovered that, despite an enormous amount of work upon the subject, many very important questions are still unsettled. Thus, there is considerable difference of opinion upon the effects of simple removal of the gland. In the author's experiment one-third of the dogs did not die; monkeys showed as only symptom cyanotic discoloration of the face, but cats generally did not survive. These peculiar results are best explained by the presence of parathyroid glands, which are really embryonal thyroid tissue, able to assume thyroid function only when a large portion of the thyroid is removed. Cats require much more thyroid than dogs, hence the parathyroid tissue is generally insufficient in amount to keep the animal alive. Under normal conditions the parathyroids probably have no functions. Urine analysis shows that metabolism is less active in thyroidectomized animal, since the soft parts of the body especially are destroyed more rapidly. Examination of the organs gave evidences of hyperemia when death set in soon after the operation and interstitial changes with a more chronic course. The effects upon the blood show themselves in a loss of hemoglobin and red cells and an increase of leucocytes. The function of the gland is probably to neutralize a substance which destroys the red cells and alters the vessel walls. If this toxin is present in large amounts, acute symptoms, such as twitchings and tetany, will follow, while with small amounts, the tissues are so altered that cachexia and disturbances in growth are the consequence. The amount of toxin does not depend on the species of animal, but upon the food; it is greatest with food rich in nuclear elements, and is thus a nucleusproteid. The lining cells of the typhoid form an iodized globulin which unites with the poisonous proteid, forming thyreotoxin, this in time is split up into two harmless principles, another nucleoproteid and an iodized globulin, which pass into the lymph and blood vessels.

Adrenalin and Liver Glycogen.—In acute adrenalin poisoning, if the animal does not die too rapidly, the amount of glycogen in the liver is diminished according to W. B. DRUMMOND and D. N. PATON (*Jour. of Physiol.*, May 3, 1904). In chronic adrenalin poisoning the glycogen is not necessarily altered. The diminution of this substance is probably the result of degenerative changes present in cells of the central zone.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the MEDICAL NEWS will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

SMITH ELY JELLIFFE, A.M., M.D., Ph.D., Editor.

SUMMER LABORATORIES.

WITH the close of the academic year research work in the various laboratories of our medical centers of necessity comes almost to a standstill, and the question for the laboratory worker, how and where to spend the summer vacation, if not already settled, at once becomes an important problem. With many the European laboratories, which remain open during the greater portion of the summer, are the ultima Thule. Large numbers, however, whose means do not permit the costly European trip remain at home and read and plan their winter's work at some quiet place in the mountains or at the seashore. Still others throw all thoughts of work to the winds and forget the laboratory in the hot, dusty city by the blazing camp-fire along the mountain stream, or amid the delights of a yachting trip, etc.

But after all the rest is to a great extent enforced, and the enthusiastic student yearns for his work, and after a few weeks of rest considers himself in banishment during the remainder of his vacation. If only he could combine his recreation with work away from the usual seat of his activities he would gladly embrace the opportunity. In this respect our biological cousin is more fortunate. For him there is the marine laboratory with all its delightful associations. Here he can enjoy the cool ocean breezes, away from the humdrum of the winter's classroom, and still work, and work, indeed, under the most favorable conditions, in contact with students and masters from far and near, the best and most powerful impetus and inspiration for research.

Is it not possible for more medical investigators to join this circle? They could only profit thereby, and perchance the biologist might also gain by the association. Surely the Grenzgebiet between medicine and general biology is sufficiently wide that workers on both sides could well occupy the same ground together. There is the great field of comparative pathology, the tillage of which will unquestionably require the collaboration of the biologist and the pathologist.

We are only now entering upon an era, in which the rôle of the protozoa in human pathology is beginning to dawn upon us, and in which the progress has been and will be painfully slow, if the medical man unaided is obliged to find his way through the maze of developmental phases in the life history of an organism, which even to the trained specialist are often so bewildering. The great good which would result from such an association cannot be doubted and is well exemplified in our country by the classical work of Councilman and his medical coworkers on the one hand and Calkins on the other.

For such work there can be no better field than the seashore or inland lake with its abundant flora and fauna. Mollusks, crustacea, echinoderms, tunicates and fishes are commonly infected with parasitic sporozoa and thus represent most valuable material for studies in this direction. Our cancer investigations would possibly be more fruitful of results if our knowledge of these low forms of animal life were more extended, and if the student of pathology could have the protozoan specialist at his side to advise and guide his research.

We should not only include the human pathologist, however, in our circle at the marine laboratory, but the physiologist and physiological chemist as well. To a certain extent the latter have already entered the fold and after a fashion have taken precedence over the pathologists, but still their number is small.

A magnificent example of what a marine laboratory should be is seen in the famous station at Naples. In our country there is Beaufort, Cold Spring Harbor, and Woods Hole, with the laboratories of the United States Fish Commis-

sion, and the many botanical laboratories throughout the country offer certain advantages as well as the more strictly zoological stations. Woods Hole has been the Mecca of the American biological student, and now, with Cold Spring Harbor, since the Carnegie Institute has granted its aid, these may become what many have been dreaming of—summer laboratories for the study of the applied biological sciences.

IS CATHETER LIFE A THING OF THE PAST?

No more serious consideration is likely to be forced upon the conscientious general practitioner than the solution of the problem how to drain the male bladder when the natural opening is partly blocked.

An eminent authority has recently stated that the mortality of catheter life should be regarded as 100 per cent. This is an astounding assertion, particularly in view of the fact that many men have been catheterized for a long period without suffering any apparent discomfort. Nevertheless, text-books, which are based on observations made four or five years ago, give the average life under the catheter as five years. It is now stated by the authority above alluded to that the period is nearer three years than five.

It becomes then a question of very grave importance, what is to be done with men who are approaching a condition which, other help failing, can be relieved only by recourse to the catheter. Are they to be advised to pursue a course of treatment which is confessed by all to have a high percentage of fatality? They cannot be allowed to continue living with undrained bladders in constant danger of ascending ureteral infection and pyonephrosis.

At the recent meeting of the American Medical Association, Syms, Goodfellow and Young reported a series of over 150 cases of perineal prostatectomy in which the average mortality was but a fraction over three per cent.

This is absolutely revolutionary. It is based upon the statements of three surgeons whose standing is such that no possible exception can be taken to the figures. The general practitioner must therefore conclude that an entirely new light has dawned on the subject of treating prostatic hypertrophy. The text-books on the surgery, which so commonly ascribe a mortality of from 20 to 30 per cent. to the operation of enucleation of the prostate, are obviously as pernicious for the practitioner as they are dangerous to the public. Their teaching is as obsolete as the most egregious inaccuracies of the old masters, and should possess for the progressive practitioner simply an historic interest. There is, however, resident in every human being, a natural antipathy to the knife, and no half-hearted physician can possibly convince the patient, who is in the very early stages, at which time conviction is most earnestly to be desired, that he should undergo an operation for the relief of a condition for which, from time immemorial the catheter has been employed. The physician himself must be absolutely convinced of the desirability of surgical intervention, for without enthusiasm on his part the public will certainly continue to live the life of their grandfathers.

Do the facts actually justify the awakening of such enthusiasm?

In the *Annals of Surgery* for June, 1904, Francis S. Watson, of Harvard, presents an invaluable sketch of the history of the operations for prostatic hypertrophy from the earliest times to the present. It is impossible to condense a tithe of what this author has to say in a short editorial note. But an acquaintance with the monograph may be safely urged upon every one who has cases of prostatic hypertrophy under treatment.

That the subject-matter is presented in a scrupulously fair and judicial manner is evidenced by the standing of its distinguished author; and that he has made a most successful effort to be conservative, surely to the point of satisfying the most non-surgical reader, will be evidenced from the following excerpt from his conclusions:

"Radical operative treatment," he says, "has not as yet reached the status at which we are justified in saying that all cases of prostatic hypertrophy should be submitted to it as soon as the condition is clearly made out, and has begun to give rise to slight symptoms. But we are justified in saying that patients should be given the benefit of it at a much earlier stage of the malady than it has been customary to apply it, and that where it is applied by those skilled in its performance, as soon as the hypertrophy can be clearly detected by examination, and if at the same time it has already given rise to well-marked symptoms, and the patient's condition is not unfavorable to the performance of an operation of this magnitude, the mortality of the operations, were they applied at that time, would be a trifling one, and their risks not nearly so great as entailed by the use of the catheter, assuming the latter to have been employed instead and under the same conditions."

To those men who are not innately averse to being convinced, these facts, as admirable an array as could well be found in the wide domain of surgery, must be convincing.

Such men will ask, "If we agree to advise operation, what technic is to be used?" Watson says: "The total removal of the gland by the perineal method is the operation of choice." There seems every reason to believe that he is correct. Only recently Young, of Baltimore, did an immense amount of his characteristically able work in exploiting the Bottini operation, but after a wide experience with it he has discarded this technic for that of enucleation through the perineum.

One impressive factor in the modern treatment is the rapidity with which the patients recover from the operation. Syms considers it distinctly disadvantageous to keep them in bed longer than is absolutely necessary, and he actually reported a series of cases in which the men were up and walking about in from twelve to thirty-six hours after operation.

The general practitioner then can conscientiously say to his patients that the operation would confine them in bed for a much shorter period than the average capital operation. What can he say to him as regards the anesthetic? It is well known that many patients dread anesthesia much more than the actual operation or even the tedious period of convalescence.

Martin B. Tinker, of Cornell, states that by using the massive infiltration method of Matas in the neighborhood of the ischiatic tuberosity, a half per cent. solution of eucaine will produce absolute anesthesia of the two nerves supplying the entire perineal region and the prostate. He has successfully and on several occasions removed prostates in this manner, the patients complaining simply of the discomfort of their position upon the table.

Modern methods and specialization have placed this operation upon a basis which is clearly unappreciated by the general profession. This ought not to be. The condition is too common a one to be allowed to be in any sense neglected. If this operation, which in every text-book is regarded as a capital one, has in truth been relegated, as it seems to have been, to the domain of minor surgery, the sooner the general practitioner knows it the better. The many victims of cystitis who constantly reinfect themselves with septic catheters should hail with delight this easy escape from the tyranny of their prostates.

ECHOES AND NEWS.

NEW YORK.

Accidents in New York.—During the year 1903 there were reported in New York City 7,912 deaths and unaccountable disappearances. Augmented by the Slocum disaster the records of the present year are likely to surpass this number by many hundreds.

Shifts Sanitary Heads.—Health Commissioner Darlington, for the second time in as many weeks, has temporarily shifted four of the five sanitary superintendents. About two weeks ago he made a sweeping change in the assignments. Last Monday he announced the following transfers: Dr. Moore, from the Bronx to Queens; Dr. Shields, from Manhattan to the Bronx; Dr. Sprague, from Richmond to Manhattan, and Dr. Murray, from Queens to Richmond.

The Sick Children's Mission.—The Sick Children's Mission of the Children's Aid Society began its work this summer in the opening days of June. Visiting physicians have been assigned to districts covering Manhattan from the Battery to Harlem, druggists have agreed to fill all medical prescriptions at cost price, and in many special cases food for sick and convalescing children is furnished from the mission headquarters. The mission also employs a force of experienced visitors, most of whom are trained nurses, to investigate the circumstances of every family in which a sick child is being treated. These visitors are required to ascertain the cause of distress, why the family is unable to employ a private physician, suggest means of obtaining employment to those out of work, and especially to give the mothers instruction regarding the management of their children and the sanitary care of their homes. Families who by reason of sickness or temporary want of employment are unable to command the attendance of a private physician are invited to apply, either personally or by postal, at 287 East Broadway.

Physicians as Inspectors of Tenements.—The public schools having closed, the Health Department physicians have taken up the "summer corps" work, and fifty doctors are engaged in inspecting the tenement houses of the city. Dr. Darlington says:

"This year, with the experience gained from last year's work, we expect to do almost untold good in the tenements. Of course, ignorance on the part of mothers as to the proper care of children is an obstacle, but gradually we hope to overcome it to a great extent. For the benefit of those mothers who do not know the rules of health the doctors carry with them cards on which is printed good advice. These cards are to hang on the walls, thus placing before the mother at all times full directions for properly feeding children. Mothers are advised to abstain from drinking beer or tea in quantities if their children are not bottle-fed. If children are fed from the bottle they are advised they be dren are fed from the bottle the parents are advised to depots. In addition to their work in the tenements, members of the corps are required to inspect the milk venders' shops, to close up all places violating the health ordinances, and to empty into the streets milk that is above the proper temperature, 50° F. Besides, they distribute coupons good for bottled milk at any of the Straus depots and in the parks or on recreation piers, and give out tickets for children's admission to the seaside hospital of St. John's Guild and to the floating hospital. I believe that the work of the corps will reduce the mortality rate this year even more than it did last year, and that with increased experience and increased facilities from year to year mortality among infants will be merely nominal."

PHILADELPHIA.

Site for State Hospital.—The commission appointed by the last legislature to select a site for the State Hospital for the Feeble-Minded and Epileptics has chosen a tract of land in Chester County, near Spring City. The land borders the Schuylkill River.

Germantown Hospital.—The new pay-patient building will be ready for occupancy the latter part of July. Ground has been broken for a new laboratory to cost $2,500, the gift of Mrs. J. D. McIlhenny. Anna T. Jeanes has given to the hospital a large lot and house.

Society of Tropical Medicine Incorporated.—The American Society of Tropical Medicine has been incorporated in the Court of Common Pleas of Philadelphia. The society is to maintain permanent headquarters in this city, but its two hundred members will be from all parts of the United States. The officers are: President, Dr. Thomas H. Fenton; vice-president, Dr. J. J. Kinyoun; secretary, Dr. Joseph McFarland; assistant secretary, Dr. J. M. Swan; council, Drs. R. G. Curtin, Judson Daland, Allen J. Smith, and W. M. L. Coplin.

Smallpox Quarantine Raised.—For the first time in three years there was a time during the past week when no place was under smallpox quarantine, and the disease in question is practically eradicated. Vaccination has been the only efficacious means of checking the epidemic. During this summer a house-to-house canvass of the city is to be made with the object of vaccinating all those who have as yet failed to comply with the request of the authorities.

List of Notifiable Diseases Increased.—After many months' consideration of the subject, the Board of Health has decided to increase the list of notifiable diseases. The revised list will include cholera, yellow fever, malarial fever, typhoid fever, typhus fever, scarlet fever, smallpox and varioloid, chickenpox, diphtheria, diphtheritic croup, cerebrospinal meningitis, measles, rubella, whooping-cough, tuberculosis (in any of its forms), pneumonia, erysipelas, puerpural fever, plague, trachoma, leprosy, tetanus, hydrophobia, and anthrax. Veterinary surgeons are required to report cases of glanders, anthrax, tuberculosis, tetanus, and rabies. In the past it has been incumbent upon the medical profession to report all cases of smallpox, diphtheria, typhoid and scarlet fevers, but under the new regulation the list is increased manifold. The most notable addition is that of pneumonia.

CHICAGO.

Sisters' Hospital Assured.—Within a few months the Columbus Hospital at Lake View Avenue and Deming Place, under the management of the Missionary Sisters of the Sacred Heart, will be an assured fact, sufficient funds having been already received to insure the success of the venture. The hospital will be five stories in height, and will be equipped with 150 rooms and 20 nurses.

Appointment of Dr. Szwajkart.—Dr. Adam Szwajkart has been appointed by Governor Yates a member of the West Park Board, to represent the Sixteenth Ward. He is a graduate of the University of Kracow, and of the Medical Department of the University of Illinois.

Semi-annual Death Report.—For the first six months of the year, according to the weekly bulletin of the Chicago Department of Health, the total deaths, 14,131, were 1,070 fewer than during the corresponding period of 1903, and the death rate, 14.69 per 1,000, was 10.9 per cent. less. There were 379 fewer deaths under five years of age—a reduction of 10 per cent.; but this decrease was entirely among those of the milk-feeding period. Of these there were 1,014 deaths, as compared with 1,660 last year, a decrease of 646 deaths, or nearly 40 per cent. The quality of the milk supply and the rarity of contagious diseases account for this marked reduction. There was a 6.4 per cent. increase of the deaths among the aged, those over sixty years old. Only five of the important causes of death show increases, namely, apoplexy, 93; Bright's disease, 106; consumption, 113; cancer, 42; and violence, other than suicide, 58. The following show the decreases indicated: Acute intestinal, 27; bronchitis, 134; convulsions, 30; diphtheria, 89; heart disease, 14; influenza, 63; measles, 221; nervous diseases, 171; pneumonia, 50; scarlet fever, 111; smallpox, 39; suicide, 52; typhoid fever, 107; whooping-cough, 187.

Low June Mortality for Chicago.—It is announced by the *Chicago Board of Health Bulletin* that the mortality for June was low. Among other things, the *Bulletin* says: "Temperature conditions during the last two months have given Chicago the lowest June mortality record, not only in her own history, but among all the great cities of the world. May averaged 57°, about 1° warmer than the record of thirty-three years. June averaged 65°, about 2° cooler than the record. The warmer May and the cooler June were especially favorable to the health of the young, and it is the mortality among the young, those under five years of age, that constitutes the most important factor of the general death rate. There were 1,745 deaths at all ages reported during the month—an annual rate of 11.01 per 1,000 of the population, and 24 per cent. less than the average June rate of the previous decade, which was 14.52. Of this total there were 430 under five years of age, or less than one-fourth (24.6 per cent.). Ten years ago, 1894, there were 2,033 deaths at all ages in the month of June, of which number 959 were under five years of age—a proportion of nearly double (47.1 per cent.) that of June, 1904. Death-rates are diminishing, health is improving, and the duration of human life is increasing all over the world—but in no other large city in the same proportion as in Chicago. This fact is becoming so generally recognized that the incredulity of a decade ago is now well-nigh overcome; that incredulity which found expression in the dictum of the most eminent vital statistician of the period, commenting on the death-rate of Chicago in 1893, that "a death rate of less than 18 in the thousand in a city of a million population is a sanitary impossibility." The city of London has a population of nearly five million; its death rate last year was 15.6 in the thousand. Chicago's diminishing death rate is due largely, if not entirely, to the conservation of the health and lives of the young—those under five years of age."

GENERAL.

American Electro-Therapeutic Association.—The fourteenth annual meeting of the American Electro-Therapeutic Association will be held at the Inside Inn, St. Louis, Mo., September 13, 14, 15 and 16, 1904. The scientific sessions will be held only in the mornings, leaving the afternoons free in which to visit the attractions of the Fair.

Doctors to Meet in Denver.—The American Academy of Ophthalmology and Oto-Laryngology will hold its ninth annual meeting in Denver, Colo., August 24, 25 and 26, 1904. Dr. Edward Jackson, of that city, is president, and Dr. D. T. Vail, of Cincinnati, is secretary.

Popular Medical Fads.—The daily press during the past week has again aired the fantastic theory that appendicitis is a natural sequel to influenza. It is now

asserted that influenza associated with a meat diet is an almost unfailing cause of the fashionable disorder.

Mississippi Valley Medical Association.—The Thirtieth Annual Session of the Mississippi Valley Medical Association will be held at Cincinnati, O., October 11, 12 and 13, 1904, under the presidency of Dr. Hugh T. Patrick, of Chicago. The headquarters and meeting places will be at the Grand Hotel. The annual orations will be delivered by Dr. Wm. J. Mayo, of Rochester, Minn., in Surgery, and Dr. C. Travis Drennen, of Hot Springs, Ark., in Medicine. Request for places upon the program, or information in regard to the meeting, can be had by addressing the secretary, Dr. Henry Enos Tuley, Louisville, Ky., or the assistant secretary, Dr. S. C. Stanton, Masonic Temple, Chicago, Ill.

Clothing as Physical Records.—An excellent illustration of the value of records has been afforded lately regarding the question of physical degeneracy. A firm in the north of England has compared the measurements for clothing made two generations ago with those of to-day, the results going to show that chest and hip measurements are now three inches on the average more than they were sixty years ago. The same conclusion is reached by the experience of the manufacturers of ready-made clothing.

Cholera Epidemic in Asia.—A dispatch from Odessa says that the Government is establishing with all haste a medical and military cordon in Trans-Caucasia against the importation of cholera from Persia. There are said to be 300 deaths daily in Teheran and that the cholera epidemic is rapidly spreading throughout Northern Persia. Minister Allen, at Seoul, says he has learned from a missionary surgeon that cholera has crossed into Manchuria and appeared at An-Tung.

Newark's Water Supply.—In his report to the Board of Health, Dr. R. N. Connelly, the city bacteriologist, shows that Newark's $6,000,000 water supply is contaminated, and that the source of impurity is at the headwaters of the great system. So far, the water taken from faucets in various parts of the city has been found to be practically pure. But the fact that impurities were in evidence in the water taken at various points in the watersheds was sufficient to alarm the Health Board, and in consequence a trip will at once be made to the sheds and a thorough inspection will be made with a view to locating the cause of the contamination.

Health of Russian Army.—An official report on the health of the army in Manchuria shows that up to June 26 the officers and men in hospital in the field reached a total of 7.136 per cent. and 3.043 per cent. respectively of the whole force. If the wounded sent to the rear were included the percentages would have been 10.24 and 6.51 respectively. After the rains began on July 9 the percentage of officers in the hospitals became 8.383 and of the men 4.646. The proportion of infectious cases rose from 2.19 to 8.52, including 1.99 per cent. of dysentery cases.

Milk Dispensaries in Baltimore.—Five milk dispensaries have been opened in Baltimore under the auspices of the Thomas Wilson Sanitarium, and modifications of milk will he supplied (three pints) at the rate of ten cents a day. The milk is intended not only for infants, those who are already sick or ailing, but also for well children, the circumstances of whose parents would otherwise prevent their securing a proper diet. A card from a physician or dispensary insures the distribution of the specified mixture to an applicant as long as required, the milk being supplied in individual feeding bottles, which are returned the following day. An experienced nurse or a physician is in attendance at each station, and in general an admirable dispensary system has been arranged to supplement the work of the sanatorium, which, during the summer months, each year cares for a number of children suffering from intestinal disorders. The possibilities of more searching preventive work through a dispensary system will be given a thorough test.

Cancer Research.—The English General Committee of the Cancer Research Fund, at its meeting in London, on July 8, made an important report, no doubt, but, we regret to say, one that carries more negative than positive information. We are simply told that cancer is not an infectious ailment, is not transmissible from one species to another, is not caused by a parasite, that radium has been found to exercise no curative effect, that a serum has been discovered from which good results are hoped and that the cancer cell can reacquire powers of self-propagation. Thus the real cause of malignant growths is yet undiscovered. That we must still submit to surgical operation as the one and last resort is the conclusion forced upon us. The greatest danger is in delaying such treatment. The Prince of Wales, who presided at the annual meeting of the committee, gave the true practical turn to the proceedings when he urged the public to *"consult the surgeons on the first appearance of any cancerous symptoms."*

The Red Cross in Japan.—The following extract from a private letter sent by an English visitor in Tokio has been printed in the London *Times:* "One admires the way the women of the country fall into their places as a support to the army medical service in the war. All the male personnel are drafted from the hospitals in the home territory and join the columns of the field army. The women nurses step into their places in the hospitals in Tokio and elsewhere, and carry on the work of nursing sisters. They are all fully trained during a three years' course at hospitals belonging to the Red Cross Society or at other civil hospitals. I recently visited the Juntendo Hospital here, and saw the system of training. This hospital, which is the oldest and at the same time one of the newest in construction, as the old buildings are being pulled down and buildings on a new plan erected, employs only women nurses, and trains them in the hospital. They go through a theoretical and practical course of about three years after they have been trained. This is only one example of the resources of the country in supplying the hospitals with trained female attendants. I have just seen a large operation at the University Hospital, where the instruments were looked after and the dressings arranged, etc., by Japanese women, and nothing could have been done more skilfully or more in accordance with the principles of asepsis. There are thousands of Japanese women of every class of society fully trained, and as expert and sympathetic as any of our own women can be, with full knowledge of their folk such as no newcomer can ever have, working under definite Government regulations in the army hospitals. Our own women might well take a lesson from them in the way they do their work, without ever considering whether they are getting kudos or not, and never thinking of gaining that sensational form of experience, for a woman, which consists in 'going to the front.'"

Remedy for Leprosy.—The London *Times* correspondent at Rangoon, Burmah, says that Capt. E. R. Rost of the Indian Medical Service has succeeded in cultivating the bacillus of leprosy. He has made a substance from the cultures which he calls leprolin, and which, when injected into lepers, has marked beneficial action, alleviating the symptoms of the disease. Captain Rost has discovered that the method of growing the bacillus of leprosy is to extract the salts from the nutrient media, and that the bacillus of leprosy will not grow in the presence of the salt. In order to make

such nutrient medium he distills beef extract soaked in pumice-stone in a current of superheated steam, and obtains a medium in which the bacillus of leprosy and, also, that of tuberculosis grows with the greatest ease. Leprolin is made on somewhat similar lines to those first employed by Professor Koch in the manufacture of tuberculin. Over one hundred cases of leprosy are being treated in Burmah by injections of this substance, and the treatment is also being tried in thirty places in India. Already four cases have been reported cured, and in the great majority of those under treatment the improvement is marked.

Railroad Accidents.—It seems, according to the annual report of the Interstate Commerce Commission, that during the year ending June 30, 1903, no less than 86,393 persons were either killed or injured on railroads in this country. Rather appalling figures, it would seem —figures that suggest campaigns and battlefields, rather than the sober report on the conduct of certain business enterprises. It is interesting and instructive to compare these figures with the showing made by the railways of Great Britain during the corresponding period. These figures are also from an official report and reflect on the American management in no flattering manner. For example, Great Britain's 22,380 miles of railways carried in 1903 nearly twice as many passengers as were transported by the 203,132 miles of railways in the United States, and yet in the United Kingdom there were only 235 collisions and derailments, as against 10,643 in this country, and only one passenger killed for every 47,793,320 carried and one injured for every 1,540,745 carried in the United Kingdom, as against the American figures given above. Conditions in the two countries differ doubtless, but conditions alone can hardly account for so amazing a difference in the railway casualty lists of the two countries. Negligence verging on the criminal seems indicated somewhere in the American system.

Doctors and Their Fees.—In a medical case which was tried in London before Mr. Justice Darling last week it was stated that the usual fee for attendance and medicine in the poorer districts of London is 6d. As a matter of fact the 6d. fee is by no means confined to the East-end. In Chelsea, for example, which is not a slum district, a doctor has recently set up a dispensary where advice and medicine can be had for 6d. In point of fees there is a curious contrast between the medical profession in England and Ireland. In the suburbs and country districts of England medical men of the highest standing often charge no more than 5s. a visit, while in Ireland doctors of the same standing never dream of charging less than £1 1s. At first sight it appears as though only the well-to-do could afford the luxury of a doctor in Ireland, but although Irish doctors consider it beneath the dignity of their profession to charge less than £1 1s. they often consider the pockets of their patients by paying four or five visits for that sum.

The Heatherside Sanatorium.—The opening by the Prince and Princess of Wales of the new country extension of the Brompton Hospital for Consumption and Diseases of the Chest at Heatherside, Camberley, Surrey, England, took place on June 25 in the presence of a large and interested gathering. In the unavoidable absence of the Earl of Derby (president of the hospital), an address to their Royal Highnesses was read by Lord Cheylesmore, in which it was stated that the foundation of the original hospital in the Fulham Road had been laid in 1844 by the late Prince Consort, and the foundation-stone of the extension wing in 1879 by King Edward VII. (then Prince of Wales), and that the institution had from its commencement enjoyed the support and patronage of the royal family. A further development of the hospital was the sanatorium and convalescent home to be opened that day by their Royal Highnesses. This new building was intended for the open-air treatment of tuberculosis and for convalescent cases from the parent institution, and was designed to provide accommodation for 100 patients of both sexes. The need for such an extensive development had been rendered urgently imperative in consequence of the advances of modern science in the treatment of consumptive patients, also by reason of the increasing impossibility of obtaining admission for such convalescent patients to any of the existing convalescent homes. The cost of the site and building, furnishing, etc., would amount to £70,000, and the maintenance of the new extension would entail an increased annual expenditure of some £10,000. Being one of the first institutions of the kind for treating gratuitously on the open-air system the poorest classes from all parts of the country, the committee felt that it was entitled to the support of the public at large.

CORRESPONDENCE.

OUR LONDON LETTER.

(From Our Special Correspondent.)

London, June 18.

THE SECRET OF PERPETUAL YOUTH—SKIPPING AS AN EXERCISE—ABUSE OF HOSPITALS—THE PUBLIC HOUSE AS A SOURCE OF CONSUMPTION—ANOTHER INFALLIBLE CURE FOR CONSUMPTION—DEATH OF A PROMISING BACTERIOLOGIST.

Professor Metchnikoff, of the Paris Pasteur Institute, is distinctly what the French call an *homme sérieux*, otherwise one would be tempted to suspect that he amuses himself by practising on the gullibility of the public. Every now and again he leads unwary persons to imagine that he has discovered the secret of perpetual youth. He has lately been unbosoming himself again on the subject of old age, which he regards as a chronic disease, the cure of which is not impossible. On this text several of our newspapers have for some days past been discoursing most eloquent nonsense. For this the Russian investigator must to a large extent be held responsible, for he throws out oracular hints as to specific serums that are to slay the microbes which lurk within the body seeking for an opportunity to lay waste the house of life. This supplies a basis on which the journalistic imagination constructs a theory that there is a microbe of old age which must therefore be regarded as a contagious disease. The new Pentacle of Rejuvenescence, when looked into, fades into the mere shadow of a dream. The serums which are to enable the organs and tissues to withstand senile decay are yet to be found, and when found their utility is purely theoretical. So far from having found a cure for old age Metchnikoff has at present nothing better to offer us as a preventive than soured milk. Apart from the degenerative changes in the kidney, liver, brain and other organs which are the expression of senile decay, the main source of danger to man, according to Metchnikoff, is his own large intestine. This is a haunt of microbes which poison the system by their baleful chemical products. His account of the intestinal flora reminds one of the description of the Upas tree breathing death to all who come within its sphere of influence. The soured milk is intended to kill this pestiferous vegetation. But the most effective remedy would be to free man from the breeding ground in which it grows so luxuriantly, by removing the large bowel

which is a superflous relic of a remote ancestry, and is now a cesspool of filth that is a standing menace to health and to life. Metchnikoff is not prepared to advocate this heroic treatment at present, but he believes that in the distant future the operation will become general. He is evidently unaware that it has already been performed by an English surgeon, Arbuthnot Lane, of Guy's Hospital, London, not exactly with the intention of making man immortal, but as a means of relieving constipation which proved refractory to treatment, and thus indirectly prolonging life. Lane's account of the process of reasoning by which he screwed his courage to the point of cutting out the large intestine is interesting. While operating on a case of recurring obstruction of the large bowel at the hepatic flexure which had been diagnosed by the patient as being due to cancer of the hepatic flexure and by his medical advisers as renal colic, he became alive to the mode in which constipation of adhesions and of a mesentery which were able to interfere very effectually with the mechanics of the cesspool of the intestinal tract. It was then apparent that the condition of the appendix was entirely secondary to that of the secum, and to obtain complete relief from symptoms it was necessary in many cases not only to remove the appendix but also to divide the constricting bands which controlled the lumen of the large bowel. This he did in a large number of cases, in many of them with the greatest advantage. He endeavored to render the benefit as permanent as possible by insisting on great attention being paid to the bowel subsequently by the use of purges, enemata, massage, exercises, etc. In a certain proportion of the cases, however, a recurrence of the symptoms ensued. He then came to the conclusion that these patients could not be benefited permanently by the treatment of effects, as no satisfactory means of dealing with them were available, and that to ensure peace and comfort to the sufferers in the future the cause of all the trouble must be removed. It was apparent that these patients lost as much by the absorption of ptomains, etc,. from the feces during the prolonged stay in the large intestine as they gained from the absorption of any nutritious and useful material. Some geographical bore complained that Francis Jeffrey had d——d the North Pole, and Sydney Smith tried to soothe him by saying that he had heard the editor of the *Edinburgh Review* speak disrespectfully of the equator. He could not have spoken more disrespectfully of it than Lane speaks of the colon. Not believing, says he, that the colon plays a very important part in the present state of civilization, he determined to divert fecal matter altogether from this part of the bowel, to convey it directly from the ileum into the upper part of the rectum, or into the sigmoid if the rectum did not lend itself readily for the purpose. He knew from the results of this operation in cases of cancer that patients of the class referred to would not be exposed to any unjustifiable or serious risk, and would not be deprived of any useful function. At first he attempted to exclude any passage of feces into the cecum by establishing between the end of the ileum and the rectum or sigmoid an anastomosis sufficiently large to prevent subsequent closure. For this purpose it is necessary to build the ileum into the large gut so that the circumference of the combined bowel shall not exceed the original circumference of the large intestine. This is done by cutting away half the circumference of the ileum and a corresponding amount of that of the large bowel and lacing together the edges of the apertures. Lane soon came to the conclusion that the only certain means of putting the large bowel entirely out of gear, when the rectum is overloaded with feces, is to make an ordinary lateral anastomosis between the ileum near its termination and the upper part of the rectum or the sigmoid as may be most convenient. After this is done the ileum is divided between the seat of anastomosis and the cecum. This arrangement is safer than the division of the ileum and the implantation of its proximal end into the large bowel. Lane says he is sure that the principle involved in the cutting off from the intestinal tract of almost the entire length of the large bowel, "which to a certain class of persons is a distinct detriment rather than a source of strength, will have a very extensive application in future in surgical practice."

Dr. Francis T. Bond, of Gloucester, has hitherto been best known to fame as the founder and energizing spirit of the Jenner Society and a sturdy champion of what antivaccinists call the "Jennerian rite." He has now come forward (in the *National Review* for June) as the strenuous advocate of skipping as the best form of exercise for the preservation of health. To most people the mention of skipping will only bring back memories of early childhood. But the trained athlete, says Dr. Bond, knows that it holds a high place in the repertory of exercises which the candidate for athletic honors of whatever kind practises in order to develop firmness in his muscles generally, capacity of breathing power and the maintenance of sustained effort. Jem Mace, a well-known hero of the prize ring in the middle of Queen Victoria's reign, used it largely to get himself into fighting condition and especially to develop agility. One of the special advantages of skipping is said to be the ease with which it can be graduated to the capacity of the feeblest tyro. It is impossible to skip except in a rhythm of some sort, "and the skipper who adjusts his movements to a definite rate per minute may be assured that in ten minutes he is expending just ten times the energy that he expends in one minute, with a greater certainty that he can have in the case of any other exercise except walking." There are, we are told, few bodily troubles except those which depend upon radical unsoundness of the vascular system, involving the risk of hemorrhage as the result of sudden exertion, that will not be benefited by skipping. For the melting of "too, too solid flesh" there is nothing like it. The result of this strong recommendation from a physician of repute like Dr. Bond, will doubtless be that numbers of elderly citizens who, like Hamlet, are fat and scant of breath, will take to going through intricate evolutions with the skipping rope in their back gardens.

At the International Home Relief Congress, held last week at Edinburgh, one of the subjects discussed was the abuse of hospitals by well-to-do people, a very sore point with general practitioners in this country. Professor Glaister, of Glasgow, said that from statistics it appeared that the number of applicants for free relief was increasing every year, and that the proportional increase was greater than was warranted by the natural increase in the poorer population. If the claim for free medical attendance were to be satisfied in proportion to the increased demand for it, a time would soon come when some step must be made either to limit the extent to which such aid was to be given, or to test the need of the applicants for such eleemosynary assistance. The need for inquiry into the fitness of applicants was so obvious that a movement in that direction had taken place in various large hospital centers. Meanwhile, something might be done by hospitals setting apart a ward or wards for patients who are willing to contribute some portion of the expense of their maintenance. The key to hospital reform seemed to him to be a method

which would insure that the functions of an hospital were being directed and kept in proper channels—namely, for the benefit of the poor for whom they were intended. Whether that method was to be found in an income test, in the establishment of provident dispensaries to which applicants for medical relief would contribute something per visit to a common fund, and in the cooperation of hospital and dispensary authorities, the general public, and the medical profession, was a subject requiring serious consideration. Dr. Clouston, President of the Royal College of Physicians, Edinburgh, said there was a danger of lowering public opinion and the self-respect of the population by such practice as the abuse of hospitals. It was a great social question, for if any community accepted, a great injury was done to the whole body politic. Dr. James Ritchie, president of the Obstetrical Society, Edinburgh, said the present system of hospital relief tended to pauperize the people. He should like to see put into operation some national scheme of insurance against sickness, such as was in operation in Germany. After a good deal of discussion the following resolution was carried: "That, in the opinion of this Congress, the time has now come when, with a view to the proper direction of charitable effort and the prevention of hospital abuse, close relation should be established between the hospitals, dispensaries, the medical profession and the public, for the regulation of indoor and outdoor relief of sick poor by the institution in every populous center of a general hospitals committee, composed of representatives of (1) hospital, dispensary and nursing boards, (2) hospital and dispensary staffs, (3) general practitioners, (4) contributors, and (5) wage-earning members of the community, for the purpose of determining, "inter alia," (*a*) the conditions of admission to hospital and other medical relief, (*b*) the collection of revenue, (*c*) the prevention of overlapping, and (*d*) such other questions as experience may suggest."

Dr. Niven, Medical Officer of Manchester, some time ago brought a strong indictment against the public-house as a source of phthisis, supporting his contention by a mass of statistical evidence. This view is shared by Dr. Arthur Ransome, who is one of our leading authorities on tuberculosis. In a paper published in the *Medical Chronicle* for May, he says the public-house, viewed from a sanitary point of view, is certainly an object of suspicion as an infective center. It not only shares the likelihood of tuberculosis contamination with other places of public assembly, but has special dangers of its own. Its bars and taprooms are usually dark, dirty and ill-ventilated. They are often overcrowded, especially in the evening, by crowds of workmen and loungers, many of them consumptives. These people spit freely both into the spittoons, containing sawdust or sand, and onto the floor. The floors are for the most part covered with dry sand or sawdust, and are only swept occasionally, perhaps once or twice a week. The sputum from their occupants, much of it charged with virulent tuberculous material, is mixed with the sand or sawdust: it is dried up and ground into fine powder under the heels of the drinkers. When it is swept up, some of it flies into the air, and floats there on delicate wings of mucous or epithelial scales. It is thus capable of being conveyed into the lungs of susceptible persons, and of transmitting the disease. Add to all this risk the probability that spray from the coughing of some consumptive may also pass into the air breathed by others, and we cannot be surprised that tuberculosis infection arises from this source. Dr. Ransome endorses Dr. Niven's recommendation that public-houses should be placed under strict legislation in regard to cleanliness, and that spitting in public-houses should be forbidden.

A retired medical practitioner of Cornwall, who is now Mayor of Dartmouth, has announced to all whom it may concern that he has discovered an infallible cure for consumption. It is scarcely necessary to say that this intimation has been conveyed to the public not through the medical journals, but through the lay press. The Mayor considers Koch's treatment entirely wrong because it is "at variance with nature." His own method has at least the merit of simplicity. All you have to do is to take bacilli infinitely more powerful than that which produces tuberculosis and inoculate the patient with them. The stronger will kill the weaker, and will then in the most accommodating spirit follow their victims into the silent land. Dr. Searle has written to Mr. Rockefeller asking for a part of the million and a half dollars which the American millionaire is understood to have offered to any one who shall discover a cure for tuberculosis. The doctor wants nothing for himself, however; what he needs is a laboratory in which to prosecute his researches. It would seem that he also requires patients on whom to try his treatment. He does not ask for doubtful cases, but for such as are practically hopeless. "Place them under my treatment," he says, "and I say unhesitatingly they will recover." He at first refused to reveal his method, saying that he was writing a book in which it would be fully known. Within the last few days he has announced that his idea is to fight the germs of tuberculosis by the aid of typhoid germs. He declares that in his experience, and the experience of many physicians of long standing, they have never met with any one suffering from organic disease, consumption or cancer, dying from typhoid fever. He gives illustrations in which, when typhoid has attacked consumptive patients they have invariably recovered, both from typhoid and tuberculosis. He advocates inoculation, according to his method, of children whose family history is pronouncedly tuberculous or cancerous.

Dr. Louis Jenner, one of the most promising of our bacteriologists, died a short time ago of typhoid fever. He had been making experimental researches on that disease at the Lister Institute, and it is at any rate possible that he has fallen a martyr to his scientific enthusiasm. One of our foremost pathologists nearly died a few years ago of typhoid fever contracted in making post-mortem examinations. Those who are curious about coincidences may be interested to know that he was a son of Sir William Jenner, whose work so largely contributed to place the doctrine of the non-identity of typhus and typhoid on an unassailable basis.

SOCIETY PROCEEDINGS.

NEW YORK ACADEMY OF MEDICINE.

Section on Genito-urinary Diseases.

Stated Meeting held March 16, 1904.

The President, James Pedersen, M.D., in the Chair.

Perineal Galvanocautery Prostatotomy (two cases).—Dr. F. Tilden Brown presented these two patients for the purpose of bringing out an expression of opinion from the members of the Section as to whether they were not now in a position to classify the different forms of prostatic obstruction so as to select and practice that form of operation best suited for the relief of the disability. He felt satisfied that the age and constitutional state of the patient should be given due consideration as well as the

size, character and good of prostatic impediment. Even where the patient was not old and in good enough health to presumably undergo any ordinary operation, the more extensive and so-called radical procedures were not necessarily always the ones offering the best remedy for the symptoms. This is believed to be exemplified with the following:

Case I.—C. G., sixty-four years old; was admitted to Bellevue Hospital Dec. 13, 1903. Discharged cured March 14, 1904. Diagnosis: Prostatic bar, causing complete retention, cystitis and abscess of the scrotum. Family history, negative. Parents lived to an advanced age. Personal history: Generous alcoholic habit; fifteen years ago, right incomplete inguinal hernia. Three years ago, incomplete left inguinal hernia. Eight years ago, because of no favorable opportunity, he permitted a day to pass without urinating. At night he found himself unable. This disability continued two more days when catheterization drew an immense quantity. For two weeks following he catheterized himself and then had so painful a cystitis as to require hospital treatment for three months. When discharged the painful character of the cystitis was cured, but complete retention has always necessitated the use of the catheter. Since the institution of catheter life he has had a number of attacks of painful swellings of the testicles. Ten days ago a similar trouble appeared on the right side, eventuating in a large abscess of the scrotum. For this he entered Bellevue Hospital. To the inner side of the abscess an indurated mass led to the diagnosis of tuberculous epididymitis. Four incisions, curettage and gauze drainage was attended with prompt healing. A streptococcus was recovered by culture. Microscopical examination of tissue and pus failed to show tuberculosis. From the time of admission an aggravated cystitis was also treated, and the conditions causing his complete retention were studied. A rubber catheter was accepted without difficulty. The urinary distance was 9¼ inches, and the urine, to the last drop, was expelled through the catheter with considerable force. Digital examination of the rectum showed only a rather flat expansion of a moderately enlarged prostate. Up to this point the inference was that a pedunculated middle lobe was the cause of retention, but a cystoscopic examination showed the impediment to be an interprostatic bar or lip. A galvanocautery incision of this and the two slightly protruding lateral lobes were believed to offer admirable promise of cure of the symptoms. The operation was done on Feb. 13, 1904. Since the preliminary steps in the technic of Young's prostatectomy and Chetwood's prostatotomy are with advantage carried out in the same way, the operator, by being equipped with the instruments for both procedures, may, in cases somewhat similar to this, defer the decisive choice until the finger has explored the bladder. Such a plan was pursued in this case, but here the sense of touch only verified the cystoscopic picture, and prostatotomy was proceded with. One median and a right and left lateral incision was made with the cautery knife. A large perineal catheter was retained for eight days. Convalescence was uninterrupted. At the end of one month the perineal fistula closed and all of the urine was voided through the urethra. The retrograded telescope of Dr. Brown's composite cystoscope shows the three furrows made by the cautery knife. Although the test of several different observers have here concurred in finding no residuum whatever after urination, he asked permission to make this test again before the Society. (In this test Dr. Kammerer kindly assisted and reported that there was no residual urine after voluntary urination.) Although the patient dates his functional disability from the time of an aggravated inattention to a full bladder there is reason to believe that for a considerable time antedating this occurrence he had been unconscious of incomplete evacuation, as is the case with many prostatics. Notwithstanding the perfect ability here shown to empty the bladder the speaker would not maintain that under the influence of certain vesical irritants enough congestion of the vesical meatus might ensue to cause temporary, moderate retention.

Case II.—H. S., seventy years old; minister; entered the Presbyterian Hospital Dec. 17, 1903. Diagnosis, prostatic hypertrophy. Family and previous history, negative. Severe cystitis, frequent and painful voluntary urination, five to eight ounces of residual urine. Present history: Eight years ago he noticed frequency of urination. Two years ago got wet and chilled during duties which offered no chance to urinate for six hours, and was then unable. He was catheterized and entered a New York hospital, where prostatectomy was advised, but declined. After a month's treatment he was discharged much improved and able to carry on his work for nearly two years without resort to the catheter. When two and one-half months before entering the Presbyterian Hospital and after an exposure similar to the first he had retention. He was now taught the use of the catheter and went South. One month later catheterization became difficult and painful. Friends and physician advised him to come North and submit to a galvonocautery operation. Only after admission to the Presbyterian Hospital, after being prepared for and within a few hours of the time fixed for a prostatectomy, did the patient definitely state this restriction. At this juncture Dr. Brown was asked by a colleague if he could operate. Both were satisfied that the conditions presenting were admirable ones for choosing a perineal prostatectomy in prefernce to any other operation. Rectal examination showed a prostate 1½ by 1¼ inches, its size most conspicuous at the apex, where on the right side it was nodular and very hard, and at the left upper apex can be felt a hard, cordlike extension, perhaps a seminal vesicle. Galvonocautery prostatotomy operation with gas and ether was done Dec. 19, 1903. On opening the membranous urethra, only after instrumental dilatation could the finger be forced into the bladder. The intravesical extension of the lateral lobes was trifling, between them a fine tight bar was stretched; three galvonocautery incisions were made, and large perineal catheters secured. Apart from vivid nightly hallucinations the patient had a satisfactory convalescence, without rise of temperature and comfortable vesical drainage. He was discharged Feb. 3, 1904, with history notes showing a considerable improvement. Residual urine now varied between two and four ounces, and a catheter, when needed, can be passed without opposition. One week after dischage he had a sudden onset of right epididymitis, with chills and fever. He was readmitted on Feb. 10; chills were repeated. Six days after admission there was epididymitis of the left side. Rest and local applications were followed, at the end of two weeks, by subsidance. On March 1, while still in bed, he had an attack of retention requiring catheterization, when 13 ounces were drawn. Antiseptic, vesical irrigation were now begun again and the patient's bladder brought to nearly the same condition as when he left the hospital; but the general constitutional state was not so

good. In this case, although lowering the vesical outlet by cautery incision probably explains lessening the quantity of residual urine and the easier catheterization prostatectomy would have given vastly better results, for the hard, irregular prostatic masses surrounding the urethra prevent any of the normal elasticity. Undue exposure to wet and cold is apt to result in sufficient congestion to again cause complete retention.

Because the case illustrated one of the rather unusual symptoms of tuberculous epididymitis and vesiculitis, which may be alluded to in the paper of the evening, yet to be read on that subject, Dr. Brown asked permission to present a patient recently referred to him with a typical urethral discharge.

Case III.—G. E. D., forty years old; merchant; first seen Jan. 29, 1904. Family history: Some relatives on his father's side had had tuberculosis. Patient's brother had been sent to Saranac Lake for pulmonary trouble. Personal history: He had always considered himself well and vigorous; had had the general diseases of childhood; had had no form of venereal disease. Skin was very susceptible to poison ivy or any irritant. Has had many attacks of herpes. In the summer of 1898, and again in 1900, without appreciable cause, he had blood in his urine. Each time he was kept in bed for about a week, when the symptom disappeared. During the past three months he has had an unusual sense of fatigue and has lost ten pounds. He has a feeling of abdominal pressure or constriction which frequently makes him take a short gasping inspiration. Friends have remarked about his pallid color. Present history: Six weeks ago, about ten days after last coitus he noticed a slight moisture at glans penis; on examining the meatus he saw a single white drop. His physician had careful examination made to determine the nature of the discharge with negative results. Various injections and internal medication have not influenced the discharge, which has never been profuse or yellow. There have been no subjective symptoms. Three days ago, on Jan. 26, while walking, he felt his clothes pressing his right testicle; examining the organ, he found it larger and much more sensitive than the left. This new development, in connection with the persistent discharge, led to his being referred to me. X-ray examination showed no lung opacities. Genital examination showed a normal meatus, a thin, mucopurulent drop just within required a platinum loop to detach. Two glass slide mounts were made, the first stained with gentian violet. Pus and mucus only were seen. No microorganisms of any kind were found. The second slide was stained for tubercle bacilli with negative result. The microscopic picture, *i.e.*, a great umber of leucocytes with a striking absence of microorganisms is one so commonly met with in renal tuberculosis as to always lend additional weight to a preconceived suspicion of the disease. Urine passed in four conical glasses: (1) clear but for one or two small filmy flakes; (2) clear; (3) clear; (4) and last decidedly turgid. Part of the fourth glass centrifuged and examined showed the same pure pus fields without microorganisms. A number of slide stains for tubercle bacilli were negative. Examination of scrotum showed superficial veins more prominent on right side, and skin noticeably warmer, evidence of a slight accumulation of hydrocele fluid. Globus minor the size of a marble and hard; no leaking of the vas (since that time slight beading of the vas has developed), but there is some edematous fulness about the right cord. Rectal examination showed prostate a trifle above normal size, slightly prominent in the median and inferior part. The right ejaculatory duct and the ampulla of the vas are enlarged and of pipe stem hardness, but not very sensitive. Neither vesicle so far as can be reached is distended or hard. Nothing appears at the meatus after the Neal examination but one-half ounce of urine now passed is turbid with pus. No appreciable spermatic fluid. Again the search for tubercle bacilli is negative. Endoscopical examination shows a normal anterior urethra. The prostatic urethra about and anterior to the caput galligaginis is edematous and congested. The features of special interest in the case are: (1) the two previous attacks of hematuria may probably have had their source in or close to the right seminal vesicle; (2) the present urethral discharge and the pus in the last portion of the urine quite certainly had such a source. The fact that the preceding two or three glasses are perfectly clear bars out any part of the urinary tract. The phenomenon then has its explanation in a compression and expression of the purulent contents of the ampulla of the right vas and seminal vesicle when toward the end of micturition the levator ani and ejaculator urinæ come into action to complete the act.

Dr. L. Bolton Bangs said that, in his observations on the use of the galvanocautery or Bottini method, he had learned that soft prostates and not large ones were most amenable to this treatment, which was often followed by brilliant success. In a general way it might be stated that a prostate in which the fibrous structures were the most developed one should not expect too much from the galvanocautery operation. He wished to reaffirm what he had so often before stated that the operation of choice was perineal prostatectomy.

Dr. F. Tilden Brown said that the different conditions which had characterized the two cases he presented were: In the first the prostate enlargement as a whole was insignificant and flat except for the somewhat wedge-shape base at the vesical neck, making it a favorable one for galvanocautery prostatotomy because of this bar at the internal meatus. Whereas in the second case a rather large, hard and irregularly nodular prostate with a base which was most prominent forward and coming well in front of the prostate urethra made any such operation futile and was a suitable case only for perineal prostatectomy.

Multiple Septic Infarction of the Kidney; Nephrectomy.—Dr. A. A. Berg presented a patient who was perfectly well until the early part of last summer, when a tight shoe caused a slight abrasion of one toe. A physician was consulted at the time and he found a slight infection of the abraded area. This was dressed and the parts healed by granulations and closed up. The abrasion had been closed about one week when the patient complained of pain in the left loin, which passed down toward the bladder. Coincident with this pain there was some fever, the temperature rising higher in the evening than in the morning. This persisted for some weeks. Then a rectal examination made by his attending physician revealed a mass in the neighborhood of the prostate, which was fluctuating and tender. A diagnosis of prostatic abscess was made and through an incision per rectum considerable pus was evacuated. The urine, so far as the patient knows, remained clear. There was no increased frequency or pain in passing water. The rise of temperature after the evacuation of the pus continued and the pain in the

left loin persisted. A diagnosis was then made of tuberculosis with a possible involvement of the left perinephritic region. There were no chills or any evidences of bladder or urinary symptoms outside of the pain in the left loin. The patient went from bad to worse and was finally admitted to Mount Sinai Hospital, where he came under the treatment of Dr. Berg. This mass in the left loin was noted and corresponded to the left kidney. It was retroperitoneal, edematous, boggy, and deep fluctuation was elicited. Rectal examination revealed the scar of the incision. The prostate itself was apparently normal; its upper margin could be palpated. The incision in the rectal wall seemed to be above the prostate and appeared to surround the left ureter. Cystoscopic examination of the bladder showed the ureteral orifices to be normal. The catheter in the right ureter obtained clear urine but an attempt to catheterize the left ureter was met with failure. The catheter was blocked one-half an inch from the ureteral orifice. He thought possibly the catheter first used was too large and attempted to pass a smaller one, but could not go beyond that same point in the ureter. The cryoscopic examination of the urine and blood showed the kidney sufficiency to be normal. The left kidney secreted nothing during the visual examination. A diagnosis was made of perinephritic abscess secondary to a kidney complication and an operation was advised and performed. The temperature on admission was above 104° F., pulse 120, the patient's condition bad. He was much emaciated, having lost 40 pounds in his illness. Two days after admission the left kidney was cut down upon and a large perinephritic abscess was evacuated. The kidney could be felt at the upper angle of the incision and a number of fluctuating areas could be easily palpated. Aspiration of its lower pole yielded pus, which contained the *Staphylococcus aureus*. No blood culture was made. Delivery of the left kidney was not done because of the danger of infection from the supperating perinephritic tissues. It was thought best to drain the abscess and allow the sloughs to separate. Accordingly a Mikulicz tampon was introduced and the patient placed in bed. For twenty-four hours the temperature declined; then the patient had a chill with rise of temperature to 105° or 106° F. During the next five days the patient had three chills with coexistent high temperature. Although the perinephritic wound was still in a sloughing condition, it was thought that any further delay in the removal of the primary focus of suppuration would be more detrimental than working through such tissues. The original wound was then enlarged and the left kidney cut down upon and pealed out of its fibrous capsule and delivered, its pedicle ligatured and the organ amputated. It was found to be studded with multiple abscesses containing *Staphylococcus aureus*. The wound healed kindly and the ligatures came away on the second week. Since operation there have been no urinary symptoms. Dr. Berg took it that the patient had multiple foci of infection, a descending ureteritis of a suppurating nature, with abscess around the lower end of the ureter. Such a periureteric abscess was incised rather than a prostatic abscess.

A New Method for Radical Operation for Malignant Disease of the Urinary Bladder.—Dr. A. A. Berg presented a woman of thirty-two years, to illustrate a new method for radical operation for malignant disease of the urinary bladder, especially of its posterior wall and floor. He first saw the patient in July, 1903. She suffered from a far advanced carcinoma of the uterus, vagina, both broad ligaments and *bas fond* of bladder. In view of her young years it seemed to him that an attempt might be made to prolong life by a complete removal of the neoplasm and the indurated uterine iliac lymphatic glands. The patient and her friends readily consented to operation, though little hope for ultimate cure was given, and though the risks of the operation were clearly stated. She was admitted to the Mount Sinai Hospital and operated upon by Dr. Berg in July last. The ureters were catheterized preliminary to the operation. The abdomen was then opened in the median line. The uterus, appendages and broad ligaments were found to be extensively involved, likewise the internal iliac glands and lymphatics, and the right posterior wall of the bladder; the right ureter passed directly into the mass. The uterus, appendages and internal iliac glands and lymphatics up to the bifurcation of the common iliac artery were removed in one piece. The bladder was opened below the peritoneal reflexion on the posterior surface just above the affected area. The cancerous tissue was excised together with the lower end of the right ureter; the proximal stump of the ureter was at once implanted into the summit of the bladder. The bladder defect was closed by catgut sutures for the mucosa and silk passed, cushion-mattress fashion, for the muscularis. The pelvic cellular tissue was drained *per vaginam* and the pelvic peritoneum completely closed. A complete closure of the abdominal wound was made. Permanent catheter was left in the bladder. The speaker was impressed with the ample space and ease of access this intraperitoneal route afforded for attacking malignant growths of the posterior wall and floor of the bladder. Furthermore, the intraperitoneal route was the only method by which the internal iliac glands and lymphatics up to the bifurcation of the common iliac artery could be exposed and removed. If these glands and lymphatics were not removed the operation was not radical and no permanent cure could be expected. The loss of blood was very little, and the shock, even after prolonged operation, was very slight, as there was no exposure of the viscera. The speaker's patient made an absolutely uninterrupted convalescence. The bladder and ureter healed kindly and there was never any leakage. The capacity of the bladder was not materially diminished. The patient gained 25 pounds after operation. She felt perfectly well until about two months ago, when she complained of some pelvic pain. Recently a recurrence of the carcinoma in the pelvis had been noted. She was still in good health and suffered very little.

Dr. Fred. Kammerer believed that laparotomy would of course give a better view of the bladder and give easier access to the seat of disease. As Dr. Berg was, no doubt, aware, this method of procedure (free incision of the peritoneum) was not a new proposition in the operations upon the bladder. Combined, in cases of cancer of the bladder, with thorough extirpation of the lymphatic glands on the floor of the pelvis, it was, according to the speaker's conviction, a very grave procedure. During the last decade more especially it had been generally acknowledged that progress toward securing permanent results could only be made, in cases of cancer, by the adaptation of methods which included the removal of the infected lymphatic glands. For example, the radical cure of cancer of the mamma, according to Halstead, gave much better results

than extirpation of the mammary gland with removal of only the axillary glands. But, he said, the operation suggested by Dr. Berg, of thorough dissection of the pelvic lypmhatics in cancer of the bladder, was not a parallel case. He said that it was well known that the peritoneum could overcome a certain amount of infection when its vitality had not been injured, but the danger of peritonitis was vastly increased by the manipulations necessary to remove the pelvic lymphatics, and this was shown by the increased mortality of Wertheim's operation for removal of cancerous uteri. In the latter operation the wound surfaces could be drained into the vagina after suture of the incisions into the peritoneum, which should even lessen the risk of peritonitis. On this account the speaker feared that the mortality of the operation for cancer of the bladder, suggested by Dr. Berg, especially in the male, would be excessively high.

Dr. A. A. Berg said that the operation of removing the glands that were situated along the iliac arteries in cases of cancer of the bladder was to be advocated; if one removed the cancerous tissues and left the glands one would do but little good. One would not think to-day of removing a cancerous breast and leaving the axillary and other glands. He said that there was no method by which we could remove these glands except by the intraperitoneal route. The operation was a difficult one and should never be undertaken before both ureters had been catheterized; this helped to distinguish them in the mass of cancerous tissue. Regarding the danger of infecting the peritoneum he did not think the increased danger could compare with the risks of leaving behind in the pelvis infected cancerous tissues. The peritoneum was opened and protected by tampons and he believed that, if done carefully, there was no great danger of infecting the peritoneum. In both his patients there were no signs even of irritation. Another advantage of this operation was that where the ureter was to be resected the implantation was easy and the drainage was from below through the peritoneum or vagina. He believed the dangers of infecting the peritoneum had been much overdrawn.

A Case of Funiculitis Following Urethritis.—This was presented by Dr. James Pedersen. The patient, twenty-nine years of age, has had four attacks of urethritis within twelve years, but gives no history of severe posterior urethritis. He came under observation at the clinic the latter part of August, 1903, presenting a scanty discharge. Under hand injections of argyrol he did well, and at the end of four weeks an astringent injection was substituted. At this time pain in the groins developed, and has continued. Shortly thereafter both urines became cloudy, and about a month later the discharge reappeared. The treatment during this interval was tonics and balsams; no injections were used. Argyrol was then resumed. Three weeks later right epididymitis developed. It began to abate after three days in bed. A week later, after hard work and a slight traumatism, epididymitis in the opposite testicle developed. All local treatment was stopped, creosote and cod-liver oil were ordered and he was sent home to bed. After he had been in bed three weeks the present swelling appeared in the left groin. At the end of a month he reappeared at the clinic, having spent in all seven weeks in bed. No instrumentation had been employed at any time. About three weeks ago on three occasions, after straining at stool, the urine was very slightly blood-tinged. There is no family nor previous personal history of tuberculosis. Under expectant treatment (cod-liver oil and creosote) the swelling has slightly diminished. The moderate purulent urethral discharge contains gonococci. One examination for tubercle bacilli has been made; the result was negative. The prostate is about normal in size, firm and its lateral borders are infiltrated. There is a marked cord-like infiltration in the region of the left seminal vesicle and ampulla; trifling infiltration at the corresponding point on the right side. Anything more than very gentle massage of this region causes blood to appear in the urine. Since last summer the patient has been very hoarse. At that time he had what was said to be a severe bronchitis. He gives a history of having worked for a year in a dusty room amid generally unsanitary surroundings. Dr. T. J. Harris, who kindly made a laryngoscopic examination, reports a small papiloma attached subglottically to the left vocal cord, which may be innocent but is probably tuberculous because of dulness and high prolonged expiration at the right apex, together with subnormal temperature.

Papillomata of the Bladder Removed by Suprapubic Cystotomy.—Dr. H. H. Morton presented this specimen which was removed from a man, forty-two years old, who had always been well up to five years ago, when he got wet and then found the beginning of his present trouble. There was pain in the back and frequent urination, with a little hematuria. The symptoms soon changed and, during the last two and a half years, he complained of frequent urination, every hour by day and three or four times by night. There was sudden stoppage of the stream while in full flow and this always caused him severe pain in the bladder. Blood was passed freely, usually for two or three days, and then ceased. One week ago he passed four fleshy masses without pain. On August 11, 1903, examination showed eight ounces residual urine. No stone was present. It was impossible to use the cystoscope because of the hematuria. Papillomata of the bladder was suspected, and a suprapubic cystotomy was performed and the specimen presented was removed. The wound healed after a very protracted and slow period of convalescence. The patient was discharged cured.

Dr. John Van der Poel asked Dr. Morton if he effected the removal of the growth with the knife or with the Paquelin.

Dr. Morton replied that he was prepared to use the Thompson bladder forceps, but he found that it was easier to remove the growths by means of the fingers, twisting them off.

Dr. R. Bolton Bangs said that one of the most interesting questions in such cases was that of recurrence and what steps should be taken in treating the base of the growth to prevent this. In those cases he had operated on, without absolutely resecting the bladder wall, he had removed the growths as thoroughly as he possibly could and then freely cauterized the bases and yet, in two cases in which he subsequently reopened the bladder on a return of symptoms, there were recurrences at the former locations. One case recurred within two years and the other the interval he did not remember. To him this question was most interesting.

Dr. Van der Poel said that one would be less likely to have recurrences if the Paquelin was used. In two cases in which the Paquelin was used there had been no recurrence in two years in one case, and in one year in the other.

Dr. H. H. Morton said the use of the Paquelin was valuable in many cases, but the free bleeding which accompanied the removal of the growths made it

very difficult to use. The blood concealed the surfaces which should be burned and it was impossible to sponge fast enough to get a clear view. Unless the surgeon saw distinctly the tissues which he was cauterizing he might destroy important structure such as the ureteral mouths or openings of the urethra.

Treatment of Tuberculosis of the Testicle.—Dr. J. B. Bissell read this paper. Will be found in full on Page 111 of this issue of Medical News.

Dr. F. Tilden Brown said he took no exception to the methods of treatment advocated because he was in accord with the views expressed. The fact that the seminal vesicles and the upper part of the vas deferens were so commonly involved in these cases of tuberculous epididymitis with but a slight invasion of the lower part of the vas made him question the direction the infection traveled. The consensus of opinion to-day seemed to be in favor of the original focus being in the lower part of the tract although those who had expressed different views in their writings during the previous decade still clung to them. He asked the reader of the paper if he understood him to say that Dr. Murphy expressed the opinion that the original primary tuberculosis of the epididymis or testis was apart from any intrathoracic or gastrointestinal lesion? If so, he must take exception to it. There was one symptom of interest which struck him as particularly notewothy, and well illustrated in the case he had shown to-night, where the bladder, kidneys and urethral tract were not involved yet pus would sometimes appear in the urine or there might be a hematuria and the first and most natural inference would be that they came from the bladder or urinary tract. They might, however, have their source in a seminal vesical or ampulla of the vas, and in some such cases this symptom would disappear after operation upon the lower genital organs. Some authors have ascribed a bladder origin to such hematuria and considered it sympathetic only and not necessitating any tuberculous lesion. Dr. Brown had not personally seen any such case.

Dr. John Van der Poel spoke of the interesting point which was first brought forth by Dr. Young, of Baltimore, treating the vas deferens by anchoring it in the upper part of the wound. Three or four years ago he had an interesting case which gave the usual history of injury to the testis and, upon examination, a sinus was found leading to what was supposed to be at the time tuberculosis of the epididymis connected with tuberculosis of the prostate gland. No bacilli could be found in the secretions from the testis through the sinus, but the diagnosis was made after massage of the gland and then examining the discharge from the urethra which showed the bacilli. In this instance he did an epididymectomy and the vas deferens was anchored in the upper angle of the wound in the groin. The case did not do well. Upon microscopical examination the pathologist gave it as his opinion that the condition was tuberculous, although a previous examination had revealed no tubercle bacilli. Of course he was apprehensive as to the result and would not have done anything had he known that the epididymis and testis had become acutely involved. The patient, however, insisted upon a thorough operation and it was only upon his insistence that he would consent to do it. He then did a complete double castration. The wound upon the left side continued to drain for months and finally closed. The tuberculous nodules upon one side of the prostate, which were quite small, disappeared. One would hardly have believed it to be a tuberculous prostate upon ordinary examination. He said that tuberculosis presented so many phases that the short time at his disposal made it difficult to discuss them under one heading. All knew that a large number of tuberculous patients did extremely well when placed upon proper general hygienic treatment, *i.e.*, tuberculosis of the genitourinary tract as well as of the pulmonary organs. It was well known that operations for the removal of a local tuberculosis did not always give good results because there was apt to be a return of the disease. In the majority of cases the results are such that we should not perform an epididymectomy, or a castration, where the prostate or seminal vesicles or bladder were involved.

Dr. James Pedersen referred to a case of primary tuberculosis of the epididymis which he had seen in consultation. The nodule was very small; there were no evidences of tuberculosis in the lungs nor in the prostate and seminal vesicles; the diagnosis was made by exclusion. The patient being a man of means and able to give himself every advantage, hygienic measures were advised for the immediate present. Two weeks later the patient consulted one of the best and most conservative general surgeons in the city, who advised immediate removal of the testicle and epididymis, and performed the operation. The case goes to prove the diversity of opinions as to the proper treatment of this condition.

NEW YORK NEUROLOGICAL SOCIETY.

Regular Meeting held April 5, 1904.

The President, Pearce Bailey, M.D., in the Chair.

A Case of Myasthenia Gravis.—Dr. L. Pierce Clark presented his case, which, in many respects, was typical and not of particular interest except that the diagnosis was made upon the myasthenic reaction and exhaustibility of the muscles of the shoulder and pelvic girdle. The rapid exhaustibility of the muscles was more marked upon the left side. The paresis that was present was very persistent and there was a remarkable variability regarding the intensity of the symptoms. The patient's expression was sleepy and there was some ptosis. The patient had been bedridden for three months and, up to two weeks ago, the condition had grown progressively worse. Then she was given thyroid and, two days later, the parents noticed a great improvement. She even then could walk down stairs and go about some. She had the gluteal walk. In addition to the thyroid she was given thymus gland, but it had not been given long enough to make a report as to its effect in this case. She also had the condition known as "dead finger." Certain of her fingers were in this typical state and was brought about by cold, exhaustion and depressing emotion. Two months ago she developed facial edema, especially marked in the lips, and which looked as if some insect had stung her; this interfered with her speech, but that slowly passed away with her other symptoms. There was also tongue atrophy which was rather atypical. Among the striking features were periodic attacks of diarrhea, which were not due to causes other than increased peristalsis. The most marked exhaustibility was in the deltoid and trapezius muscles. The voice showed the peculiar nasal tone of the exhaustibility in these cases. The quadriceps extensor was but little involved. She has had "dropping

spells" in the streets. There was some difficulty in swallowing in the past, but now was much improved. There was a weakened hand-grasp on both sides. The galvanic and faradic currents do not get good responses in these cases.

Dr. Graeme M. Hammond asked if an examination had been made of the muscular tissue.

Dr. Clark answered that the patient objected so to such an examination that it had not been made, but he thought that in time he would get her to consent. The blood examination had not yet been made. He said that Dr. Henry Hun, of Albany, had suggested that there might be some irritation about the thymus gland which stirred it up into activity, giving rise to this condition. Dr. Clark did not think this was so because the thymus had been found to be normal in so many of these instances.

Tuberculous Meningitis.—Tubercle of Inferior Olive.—Dr. L. Pierce Clark presented this specimen, which was removed from a patient fourteen years old who had been referred to him by Dr. F. M. Cook on February 28, 1904. Headaches had existed for the past four months, the girl was staggering for the past three weeks and vomiting had occurred on rising in the morning. The family history was negative aside from the father's dying from chronic alcoholism. The boy was bright, intelligent, and well developed for his age; he appeared dull at the examination. The cranial nerves showed an unequal and irregular weakening in the following nerves of the right side, seventh, eighth, ninth, tenth and twelfth. Dr. Holden made an eye examination and reported the disks normal. There was bilateral ataxia in all movements of the upper and lower extremities. He walked a little to the right. The gait was markedly cerebellar, knee-jerks were bilaterally exaggerated, true ankle-clonus was present at times, but there was absolutely no Babinski at any examination. Big toe flexion was, however, slower on the left side. On March 1 the patient became delirious, would eat nothing and showed the first signs of a marked rise in body temperature. There was slight persistent pain over the right mastoid. The patient was referred to Roosevelt Hospital. During the next week he had a continuous temperature ranging between 101° and 102.5° F. and for the most part he was in a semi-delirious condition day and night, suggestive of basilar meningitis. The blood count showed no leucocytosis, and two lumbar punctures were completely sterile. The diagnosis of solitary tubercle in the lower right half of the fourth ventricle and a more or less diffuse basilar meningitis was held as the most tenable pathological lesion to explain the symptoms. As a last resort an operation in two stages was advised to relieve pressure and possibly later to remove a portion of the tumor. The first step was performed by Dr. Brewer in nine minutes. The patient stood the operation well, but died the following day.

The report of the brain tumor found at autopsy was as follows: There was marked opacity of the pia at the base, most pronounced in the region of the Sylvian fissure, the anterior and posterior perforated spaces and the crura. The opacity was composed of minute whitish pin-points scattered unevenly and most numerous in the areas indicated. In the position of the right inferior olive there was a mass about the size of a small hickory-nut. Its contour was not perfectly regular, generally oval, consistence markedly increased, and it was ultimately blended with the surrounding nervous tissue.

Dr. Pearce Bailey asked if a section had been made of the tumor.

Dr. Clark replied that he had tried to keep the tumor in its external appearance and, therefore, no sections had been made of it.

Case of Brachial Birth Palsy.—Dr. A. S. Taylor presented this patient. The boy was born after a dry labor, with instruments and after a great deal of traction had been made. The child was born greatly asphyxiated and it took some time for his recovery. After that it was found that he had paralysis of the right arm. During the first few months of life there was no improvement in the condition, but, during the next one or two years, there was a slight improvement in the muscles of the right upper extremity. There was a cessation in the improvement from two or three years ago and, from the time he say him, about ten months ago, the condition was as follows: There was a marked internal rotation and contracture at the wrist. The deltoid showed paralysis and considerable atrophy with displacement downward of the head of the humerus perhaps one-half to one inch. He said the muscular changes and the reaction would be referred to by Dr. Clark in his paper. In the paralyzed muscles there was the reaction of degeneration and a great deal of atrophy of them. There was a marked lack of development between the bones of the two sides. There was 2½ cm. difference between the clavicles and there was also a difference in the length of the humerus and bones of the forearms. Operation was performed nine months ago. A very interesting thing was noted in this instance. The anterior nerve division derived from the junction of the fifth and sixth cervical roots was torn away and displaced downward 2.5 cm., and was adherent to the front of the scalenus antisus by firm fibrous adhesions. The nerve was dissected free and its damaged ends removed. The junction of the fifth and sixth nerves and the posterior division derived from them was the seat of cicatricial enlargement and induration. The damaged tissue was excised, the freshened ends satured, Cargyle membrane wrapped about the junction and the wound closed as usual. The patient was placed in a dressing which approximated the shoulders and neck and this attitude was maintained for three weeks. Then the dressing was removed and the patient was allowed freedom of his extremity and was encouraged to move it as much as possible. From then on, under the supervision of Dr. Clark, he had received electricity and other treatment to develop the general condition of his muscles and made to use his muscles himself. For three months there had been more or less complete paralysis in all muscles supplied by the fifth and sixth cervical nerve roots. Now there is absolute return of nerve function. Before operation the hand had alays been held in a markedly contracted position and there had been ulnar deflection. The return in the musculo-spiral nerve function was most slow. The posterior dislocation of the humerus was very marked two months ago and there was still a spontaneous rotation and reduction now going on. The patient had not yet much rotatory power.

A Case of Obstetrical Palsy.—Dr. Royal Whitman showed the case of a little girl, nine years old, who had a posterior rotation and displacement of the humerus. She was first seen last summer after she had been going for three months to various clinics. The humerus was rotated backward and there was anchylosis at the shoulder-joint. The treatment adopted formed the subject of his paper, *q.v.* The first treatment consisted in efforts at replacement of the displaced bone. One extremity was much smaller than the other as also was the size of the

scapula. He showed the Section the amount of power that had been acquired in the deltoid. Supination was quite marked, but there was a limitation of flexion which was quite marked after the arm had been replaced. The patient was still under treatment, and Dr. Whitman demonstrated the method of overdistention, outward rotation, extension of forearm, supination, etc. It was in fact a demonstration of forcible manipulation which was absolutely necessary in the treatment of these patients. The improvement in this patient had been very marked and he believed that eventually there would be recovery. He said that reposition of a dislocated shoulder would not cure the nerve lesion, but would make it possible.

A Case of Obstetrical Paralysis.—Dr. Royal Whitman also presented this patient, a woman. The arm of one side was about three and a third inches shorter than the other. A diagram he presented showed the condition seen last summer. The patient now wore an apparatus during the day which kept the fingers in extension. There was great improvement in the condition of the fingers. This was an extreme case of obstetrical paralysis.

A Case of Obstetrical Palsy.—Dr. Royal Whitman also presented this patient, which was even more serious than the others. The original paralysis was on both sides in the arms. There was a great difference between the two extremities. Until two months ago the patient could use only one hand to dress herself, under appropriate treatment there was noted an improvement.

A Case of Obstetrical Paralysis.—Dr. Royal Whitman presented this patient which illustrated a form of posterior luxation and resistance to outward rotation. He said that if one expected to get good recovery from the employment of manipulation one must first overcome this resistance to normal motion.

Brachial Birth-Palsy and Its Surgical Treatment.—Drs. L. Pierce Clark and A. S. Taylor presented this communication, which was in the nature of an abstract and was intended only to cover the *principal* facts brought out in a study of brachial birth-palsy. A detailed account of the data would be published in full at a later date. While the clinical diagnosis was quite clear, its etiology was still mooted, although it was almost universally believed to be due to tension or compression of the fifth and sixth cervical roots. Tension probably played much the greater rôle in the causation although both factors had been proven causative agents both in clinical and experimental work. As a rule there was given a history of force having been applied during the birth of the child. In some various abnormal presentation had been present. In all the cases that had come to their knowledge there had been either a history of traction, or else this factor could not be excluded. The one and constant factor in its production, in their opinion, was traction, produced by forcible depression of the shoulder while the head was bent to the opposite side and rotated; in this way the cervical nerve roots were overstretched, causing rupture of the nerve fibers over a considerable length of the nerve, or in some cases complete rupture of the nerve. The lesion was always in the fifth and sixth nerve roots, frequently also in the seventh and occasionally in the eighth and first dorsal. From a brief review of the clinical picture of brachial birth-palsy, its etiology and pathology they said that one was impressed with the inadequacy of the present medical treatment. Surgical intervention naturally suggested itself, such as had been done in peripheral nerve injuries in general. Few secondary operations had been done upon the brachial plexus. During the past year they had operated upon four cases of brachial birth-palsy. Details of the operation were given by Dr. Taylor in his discussion. A relation of the four cases here followed. Fatal results occurred in the first and fourth cases and this brought forth the question of the degree of shock involved in the division of large nerve trunks near their spinal origin. In the first case the length of the operation, and the fairly large loss of blood incident to it, obscured the problem. In the fourth case the operation was much shorter, the loss of blood slight, and the damage to the nerve much less. Still the result was practically the same, though not so rapid. The time consumed in all four operations was unquestionably too long, but this was due to (1) unexpected conditions demanding careful dissections; (2) the delicate manipulation necessary to the handling of nerve tissue; (3) lack of skilled assistance. The following conclusions were presented:

1. The most important etiological factor in the production of brachial birth-palsy was direct or indirect tension of the nerve trunks which cause rupture of nerve fibers.

2. An explanation of the persistence of the palsy was clearly based upon the pathological findings which consisted of a destruction of the axis cylinder by rupture of the nerve fibers and formation of an overgrowth of connective tissue between the torn nerve ends through which the nerve fibers cannot regenerate.

3. The nature of the lesion in all typical severe cases demanded excision of the damaged nerves and suture of the good ends at the earliest possible moment, as in the treatment of peripheral nerve injuries elsewhere.

4. From the surgical viewpoint the desirable time for this interference was not yet determined. It would, however, seem to be much later than two or three months after birth, as Kennedy advised.

5. The present medical treatment consisting of an application of massage, electricity and systematized muscle movements should follow the surgical interference.

6. The prevention of this serious lesion of the brachial plexus rested with the obstetrician who should not stretch the child's neck in the process of delivery.

Remarks on the Surgical Treatment of Obstetrical Palsy.—Dr. Royal Whitman read this paper (see preceding page).

Dr. Alfred S. Taylor opened the discussion by stating that the question of prophylaxis was the most important in the consideration of this subject and, in order to have an intelligent grasp on the prophylaxis one should know more regarding the etiology of the conditions met with. The books state that pressure upon the clavicle during birth, hyperextension of the arm, pressure of the forceps, pressure of the fingers, etc., during birth will cause the condition. In the later literature it will be found that tension is the chief factor. If one could give an exact etiology one could make great advances in prophylaxis. For this purpose he had had the privilege of examining many newly-born infants to determine whether he could find an exact etiology. He experimented on eight children, using great force in pulling on the neck away from the brachial plexus and, no matter how hard he pulled, there always seemed to be present a pad of muscular and fatty tissue in which the nerves could sink and it seemed to him that any damage to the brachial plexus from

the application of such a force was only theoretical. He took stillborn children and placed them in attitudes assumed during the process of delivery; then pushing back the clavicle he could not get even enough pressure to cause any marked tension of the nerves. Placing the arm back of the child's head did not place the nerves on sufficient tension to cause any damage. While the arm was in that position, the forearm was firmly grasped and the fifth and sixth nerve then were sufficiently loose that they could be moved. Anything which depressed the shoulder and increased the distance between the shoulder and the neck caused greater tension of those nerves. In the living child one could place the finger between the anterior scalenus muscle and the nerves when they would feel like fiddle strings. This forcible depression of the shoulder first caused a tension of the fifth and sixth nerves and it was demonstrated that they would give way in the same position in which they were found in other cases upon which he had operated. First the fifth and sixth nerves would give way, then further pulling would cause a similar damage to the seventh nerve. It seemed to him his experiments proved distinctly that the etiology of this condition was purely that of tension and, therefore, the question of prophylaxis should be considered, and this consisted in exercising care *not* to pull the head away from the shoulder when the latter was fixed, or *not* to pull on the shoulder away from the head when that was fixed.

Erb's Palsy at Sloan.—The resident at Sloan reported six cases of Erb's palsy. In one, the presentation was a normal vertex, with delay after the head was born. With but slight pulling the shoulders were delivered and following this there was a double paralysis of the arms which soon disappeared. It was of the Erb type. In another case of Erb's palsy the hand had been placed under the neck and, after delivery of the head, had pried upon it, so producing the condition. In the other four cases, they were all breech presentations. He said that one could readily see that if the forceps were applied to the head and force exerted when the shoulders were fixed, one would produce exactly the same condition of affairs as was noted in his experiments. Again, in breech presentations, if one pulled upon the legs before the arms were delivered, there would be no traumatism to the brachial plexus; but when the arms were delivered, if the fingers were placed over the shoulders and traction made upon them, when tension would be brought to bear upon the plexus. In hooking the fingers over the shoulders the tips of them rest upon the nerve cords themselves and, if any tension was produced, it would be a greater tension and a greater lesion would be produced than if force had been applied without the finger tips over the nerve cords. He believed that this was the reason so many more cases occurred in breech than in vertex presentations. Again, it was a question with him whether the bringing of the child's body over upon the abdomen of the mother, so producing extension of the neck, would not produce the lesion. He had experimented upon this and found that the nerves were not made very tense, certainly not enough to cause them such injuries. He said that a considerable degree of force was necessary to produce rupture of these nerves. He emphasized the fact, that in the delivery of every child, one should use a reasonable amount of caution to prevent these birth palsies. Another interesting feature noticed when operating was that not only was the nerve trunk itself damaged, but also the deep cervical fascia, and this fascia was found to be adherent to the nerve trunks. He said that only recently he had seen a patient at the Vanderbilt Clinic which showed the same manner of traumatism and the same results as those that had been reported. Frequently one saw instances of men who had fallen from a height and struck upon the head and shoulders and the resulting paralysis could be likened to that occurring in birth palsies, with the paralysis and atrophy of certain muscles. Pressure upon the branches of the fifth and sixth nerves revealed, in such instances, a marked degree of tenderness. It was the stretching of these nerves that caused the lesion. He said it was worthy of comment in the operation proposed to refer to the importance of the suprascapular nerve. In his first two operations he did not appreciate the value of this nerve in the ultimate results. It was rather small in children, but it controlled largely external rotation of the humerus and, therefore, one should use caution not to get it in line with the nerve sutures. It seemed to him that from the findings which were shown in the microphotographs, one could scarcely feel that a case of well-marked Erb's palsy could be cured without exsection of the nerve and suturing of it. Dr. Whitman's paper, he said, treated of the reduction of the deformity before other measures were applied to the nerves for their regeneration. He said a reposition of the dislocated shoulder could not bring the muscular tissue into action if such tissue was not innervated.

Dr. B. Sachs said the subject was a most interesting one, as well as a very serious one and that it was very necessary that one should have a clear understanding of many of the points raised. It should first be clearly understood that not all obstetrical palsies were cases of Erb's palsy, because, he believed, there were many obstetrical palsies that had nothing to do with the fifth and sixth cervical nerves; there were many instances in which traction upon the arm produced luxations and subluxations, and the pressure of the head of the humerus was at a point lower down than the fifth and sixth nerves. Therefore, he thought, one should be careful in claiming that this method of operating was going to be a panacea, or one method of cure, for obstetrical palsies. He said there was a natural mode of recovery in obstetrical palsies, even in those cases which appeared to be extremely severe from the time of birth. It was very important to watch these cases from the earliest times. He had been in a position to see obstetrical palsies from the day of birth, and had been able to follow them for years afterward; he had had several children under observation. What he wished especially to impress upon them was that if they examined many cases soon after birth they might find a distinct subluxation of the head of the humerus probably below the deltoid which might possibly be identified with Erb's palsy; therefore, all cases of obstetrical palsies were not Erb's palsies. In one of his own cases a great deal had been accomplished by careful treatment by the early application of electricity, which was really another valuable form of gymnastics, and the intelligent use of massage. That so many of the cases did so well, reduced the question, he thought, to what would be the proper time for operation, and this seemed to him to be a very serious matter for their consideration. If one operated early there was then a tremendous amount of shock. Could one expect more from operation than from the inherent recuperative powers of the nerves and muscles themselves? He believed that if there was muscular atrophy and a great deal of wasting, especially about the shoulder, no amount of suturing of nerves, or transplantation

of their divided ends, would bring about thoroughly satisfactory results. In one of the cases presented he could not satisfy himself that there was the least deltoid action; the child exhibited nothing akin to deltoid action. He said he did not wish to discourage the operation in the least because he was ready to believe that, in carefully selected cases, they might be benefited by operation. But, he said he was much puzzled regarding the proper time for operating. When should this treatment be undertaken? that was the question. The remarks of Dr. Whitman, he thought, were quite *apropos* and entirely correct. Much of the trouble was due to secondary changes in the muscles and ligaments about the joint, and this must be overcome before anything much could be expected from the surgical interference. He believed the operation was a dangerous one; aside from the hemorrhage and its consequent shock one should bear in mind the proximity of the cervical portion of the spinal cord which adds to the danger. He hoped that the operation would prove beneficial, but because many cases did well without operation he was reluctant to resort to this surgical procedure at present when it was attended with such dangers.

Early Operations.—Dr. Carmalt spoke of patients that had been operated on before the fourth week of life. In one the fifth and sixth nerve roots were torn from the spinal cord and nothing could be done and the child died one month later. At autopsy it was demonstrated that the fifth and sixth nerve roots were torn from the cord itself; they were shredded out. The traumatism at the time of operation did not seem to be very great. In the second patient the point of division was not at the point referred to by Dr. Taylor. It was only when these nerves were under some tension that they were liable to rupture. A little over 60 pounds pressure was found to be necessary to break the nerve and he said that few obstetricians used that amount of power. At the hospital it had been demonstrated that one case required 60 pounds and four others required between 80 and 100 pounds pressure before rupture occurred. In the third patient rupture of the nerve took place and was a transverse rupture. It was easily sutured and the child did well for six months, but died of an enteritis. Operation was done during the third week of life. The child had apparently recovered the use of the arm, but whether the nerve would ever have fully regenerated was a disputed point. The fourth patient died of sepsis, five days after operation. He did not think the question of shock in the older cases was of such importance as in early life. One manipulated the spinal cord in spina bifida, where the trunks were larger than the fifth and sixth cervicles, and the amount of traumatism was as great, if not greater, and yet no apparent shock resulted. Hemorrhage should not influence the shock greatly because it could be so readily controlled. He thought that the time to operate in these cases of birth palsies would be somewhere between the fourth and fifth month and not so late as the second or third year.

Dr. Terriberry believed that any contribution to this subject would be greatly welcomed. So far the reports of operations for birth palsies showed it to he a very serious performance. He said that undoubtedly there were many cases which were not the result of stretching and he had in mind a case in which the end of the forceps impinged upon the fifth and sixth cervical roots, a very unusual thing. This case rapidly and completely recovered. This was a case of simple traumatism. He had had under observation a case of double palsy of the Erb type which followed a breech presentation and it was not in any way produced by traction. The trouble here was due to pressure upon the cervical roots. This child rapidly improved and both arms became about equal. The question raised by Dr. Sachs he thought a very important one. Everybody knew that these cases, if they improve, will improve slowly for a great length of time. The manipulations brought out by Dr. Whitman he believed to be a great aid in the cure of these patients. He believed the whole question resolved itself into the making of a correct diagnosis as to the cause. A number of cases were undoubtedly due to pressure, traumatism being applied low down on the plexus. To operate upon such cases he believed would be unwise. If by any possible means one could determine that the nerves were torn then the sooner the operation was done the better.

Dr. William M. Leszynsky said that considering the inherent power of the peripheral nerves to undergo regeneration, and in view of the fact that this was a dangerous procedure, he believed it would be wiser to wait for some time, keeping the arm in proper position, before one should resort to such a dangerous procedure. He said he would hesitate very much before he had any of his patients submitted to operation, at any rate early in life.

Dr. B. Sachs said he did not think any one had a moral right to operate upon these children before several months had been allowed for their cure by other than operative means, because the operation was a dangerous one and a chance should be given to the child to recover by natural means.

Time Best Suited for Operation and Technic.—Dr. George E. Brewer thought that enough pathological material had been presented to enable the profession, in a certain number of cases, to say positively that a rupture of the nerve or nerves had occurred and, in those cases which presented the Erb type, it was obvious that no perfect result could be obtained unless some reestablishment of the nerve trunks was made. The question as to the gravity of the operation, he believed, should not be considered at the present time, when only a few operations had been undertaken. He referred to the history of gall-bladder operations, or appendicitis operations, etc., of their early failures and early high mortalities; yet when the technic was improved and they had more experience with such cases, the mortality was greatly reduced, from 50 and 60 per cent. down as low as two per cent. Therefore, he did not think it right, in view of the few operations reported, to say that this operation was a particularly dangerous one. In one of Dr. Taylor's cases there was hyperpyrexia, the temperature going to 106°, 107° and 108° F. and this, in the presence of a sterile wound, he considered rather unusual. It resembled the temperature following thyroid operations. He said that unquestionably the operation could be performed with a much lower mortality when they had improved their technic, for children, as a rule, bore operations well. He said that Crile had demonstrated that by cocainizing the nerve trunks shock could be diminished tenfold. He had no doubt but that better results could be obtained after more operations had been done.

Regarding the time for operation in these cases he said that all who had seen nerve division and suture recognized the fact that the best results were obtained operating soon after the injury took place as possible. The sooner the better. Therefore, if surgical procedures were to be carried out they must be done

relatively early. He believed that complete atrophy of the muscular fibers precluded the possibility of operation.

Dr. Wisner M. Townsend said that the causes of death in these cases might be due to various unknown causes which may be eliminated in the future. There might be something in the method of operating which would reduce this high mortality if eliminated. If it could be determined that rupture of the nerve had actually occurred then he thought combining the method suggested by Dr. Terriberry and that of Dr. Whitman would be very advantageous.

Dr. Pearce Bailey said that it seemed to him that the question gathered itself up into the matter of the time of operation. Those cases that were operated upon early seemed to do well, but when they were operated upon late, he questioned if anything was to be gained. A paralysis that had existed two years or more did not offer much hope from operation. The fact should be borne in mind that very frequently the case is beyond the scope of operation. Statistics show that when the nerve roots are severed from the spinal cord there is nothing to be hoped for from operation. Many cases recover late and often one might operate upon a case that would have recovered without operation. He said that upon these two points the question hinged and more cases should be reported before anything definite could be decided.

Dr. Thomas P. Prout said that if the nerves were involved in foreign tissue it was impossible to repair the condition except by surgical means. There certainly was a certain number of cases that should be turned over to the surgeon.

Dr. L. Pierce Clark, in speaking of the various types of palsies, said that often one could disclose the particular type by palpation; also by noting the muscles paralyzed, the atrophy, the deformed arm, etc., all would give definite information where the lesion lay. With regard to spontaneous recovery occurring he said that everybody took advantage of that after a certain length of time. After two or three years, when atrophy had occurred and the muscles had undergone marked contractures, deformity was produced. The exact time that operation should be performed in these cases he could not say. But there was one thing certain that they did not intend to do the operation under one year of age. He said he was glad to hear what Dr. Whitman had stated regarding replacing the humerus and overcoming the contractures and he hoped such information would enable them to bring out better results in the future. He thought that overcoming these old contractures and replacing the head of the humerus was a necessary adjunct.

Dr. A. S. Taylor closed the discussion by stating that if he had known the exact condition of the first child operated upon the child would be living to-day. The operation was a prolonged one and there was much hemorrhage. The question of hemorrhage should always be considered in the operative treatment in these cases. The second patient that died was in a very bad condition and had been in the hospital for months with recurring attacks of dysentery. The dysentery following the operation materially hastened the child's death so they could not blame the operation for the death in that instance. In selected cases he did not consider the operation a very dangerous one, as it seemed to be from the statistics. The question of hemorrhage could be readily disposed of because there was really but two small blood vessels that were cut.

Dr. Abrahamson, in speaking of the cause of death in the two patients, said the relation of the cervical cord and the sympathetic system should be borne in mind. Hyperpyrexia and thyroidism could be explained by the connection between that part of the cord and the sympathetic system.

BOOK REVIEWS.

La Rhinoplastie. Par Ch. Nélaton et L. Ombrédanne. G. Steinheil, Editeur, Paris.

The subject of rhinoplasty has always been a most interesting department of plastic surgery, partly through the very wide scope for individual ingenuity the operation involves and partly through the early date at which many of the procedures were elaborated. Seductive as the technic of reproducing a missing nose has always been to surgeons, it must be admitted that the results are usually very mediocre and there is some justification for the frank brutality of a saying attributed to Dertonvilliers to the effect that in these cases the surgeon does but substitute for an infirmity that is disgusting one that is ridiculous.

In the present volume the subject is treated with the utmost attention to detail. The historical aspects of the different methods are entertainingly indicated and the steps of the operations advocated by scores of surgeons are very clearly given in nearly four hundred cuts. The inadequacy of attempts to replace complete defects merely with fleshy flaps is pointed out and in addition to many others, one most ingenious method is described in which a portion of the cartilage of the eighth rib is transplanted under the periosteum of the frontal bone and later is utilized in the frontal flap which forms the new nose.

Guy's Hospital Reports. Edited by J. H. Bryant, M.D., and F. J. Steward, M.S. Volume 77, being Volume 43 of the Third Series. J. and A. Churchill, London.

Guy's Hospital Reports always contain some very interesting material of clinical importance. The present volume opens with an article on disease of the heart due to overindulgence in alcoholic drinks, by Dr. W. Hale White, in which what is sometimes known as the Tübingen or München heart is especially discussed. This is a form of dilatation of the heart which has been found very commonly in these two cities, as also in other parts of Germany, in which the history of the patients shows that they have been free drinkers of malt liquors. The amount imbibed by some of the patients would seem almost impossible, except to such as have had experience with men working in breweries. Thirty-five liters or even more, that is to say, something over twenty quarts, are sometimes consumed in twenty-four hours. This form of heart disease has been found in other countries, since attention has been called to it in Germany.

Other interesting articles in the present volume are those on a contribution to the history of the intravenous injection of drugs, by Dr. J. M. Fortescue Brickdale; Eosinophelia in Skin Diseases, by Herbert French, and some cases illustrating the influence of Heredity in angioneurotic edema, by C. A. Ensor, in which a series of family cases of this affection is described.

ORIGINAL ARTICLES.

SOME SURGICAL ASPECTS OF OBSTETRICS.[1]

BY WILLIAM S. STONE, M.D.,

OF NEW YORK;

CHIEF OF CLINIC AND INSTRUCTOR IN GYNECOLOGY, COLUMBIA UNIVERSITY; ASSISTANT ATTENDING GYNECOLOGIST, GENERAL MEMORIAL HOSPITAL; ATTENDING SURGEON, SOCIETY OF THE NEW YORK LYING-IN HOSPITAL.

Two articles in the *New York and Philadelphia Medical Journal,* one by Dr. R. L. Dickinson, entitled, "The Best Time for Repair of Lacerations of the Cervix," the other by Dr. G. H. Donohue, on "Primary Trachelorrhaphy," contain some excellent observations, particularly that of Dr. Donohue, as to the effects of cervical laceration upon uterine involution. So far as they emphasize the importance of early surgical treatment of parturient injuries they are of great value, but in setting as a definite time for such treatment only the few days immediately following labor, certain surgical principles are overlooked, for the best application of which a wider interpretation of the facts is necessary.

The constant occurrence of cervical lacerations, even in apparently normal labors, is, of course, well known, although on account of our present aseptic technic they are less constantly of clinical importance than heretofore. The less frequent appearance during the past few years of the extremely indurated and eroded cervix is a fact noted by so experienced an observer as Dr. T. A. Emmet.

Injuries to the cervix, however, of such severe character as to cause immediate and subsequent symptoms are of very constant occurrence under the following circumstances: (1) Premature rupture of the membranes. (2) Application of the forceps and all operations requiring rapid dilatation of the cervix. (3) Meddlesome attempts to hasten the dilatation manually in normal cases.

1. *Premature Rupture of the Membranes.*—The cervix is always torn more in cases of dry labor, and in such cases it is the duty of the attendant to see how much of an injury has resulted.

2. *Application of the Forceps and Other Obstetrical Operations.*—The forceps is applied in a very large number of cases before dilatation is completed. A common expression that the rim of the cervix can be felt, but that it is soft and dilatable, means that the cervix will be deeply lacerated. After versions and in all cases where the cervix must be dilated rapidly the same injuries constantly result without regard to the operator. Manual dilatation is a misnomer; manual tearing is a more correct expression of the actual result.

3. *Meddlesome Attempts to Hasten the Dilatation of a Cervix,* perhaps already thin and soft, frequently transforms it into a thick and resistant circle which not only delays the labor but makes a deep laceration certain to occur.

Preventive treatment must be based upon an appreciation of these facts. Treatment of the injuries after their occurrence should be regarded from the same points of view as wounds in any other portion of the body, namely—hemorrhage, sepsis, disturbance of functions and subsequent disease.

Hemorrhage from cervical wounds is generally considered as of comparatively rare occurrence, but the writer's own observations have taught him that hemorrhage from this source, after labor is completed, is more frequent than from any other portion of the genital tract. One need but hold the fundus of a well-contracted uterus in a dozen operative cases and closely observe the amount of bleeding to appreciate this fact. The bleeding from the torn cervix in placenta previa frequently precipitates a fatal result. The two common obstetric procedures—douches and iodoform gauze packing—are of little value. In fact, I believe the cervical wound is often kept open and the hemorrhage is worse than it otherwise would be. Dr. Dickinson gives as one of his reasons for not suturing the cervix at the end of delivery the obscuring of the operative field by the blood. The surgeon usually considers bleeding an important reason for closing a wound.

Sepsis.—It is generally recognized in surgery that one of the best ways of preventing infection of wounds is to suture them. The cervical wound is a very frequent source of infection as may be learned by a careful local examination of septic women. If not fatal, such an infection almost always results in the hard and eroded cervix as seen by the gynecologist.

Disturbance of function from these injuries is often shown by subsequent sterility and menstrual difficulties. Subsequent disease—subinvolution—metro-endomometritis, etc., are well known. If the uterus without the presence of fever involutes insufficiently during the puerperium it is due in a very large proportion of cases to a cervical injury to which injuries of the perineum are ordinarily second in importance.

Why, then, should such injuries not be treated surgically as often as are the perineal wounds?

Dr. Dickinson says "the conditions for repair of the torn cervix immediately after delivery are as wrong as they can be, because (1) it is swollen, distorted and stretched beyond recognition; (2) because bleeding obscures the work; (3) because deliberation and due care are impossible." He would limit such work to those cases in which

[1] Received for publication April 9, 1904.

the injury causes severe bleeding. The cervix, of course, is swollen, but to say that it is distorted and stretched beyond recognition expresses the condition in exceptional instances. He refers also to Webster for support to this statement, but Webster in his own description of a plate made from the uterus shortly after death simply expresses the difficulty of recognizing in his specimen the relations of the internal and external os. That, however, is not the same as looking at a cervix which has been pulled down to the vaginal entrance by volsellum forceps. Dr. Dickinson's third objection in regard to the impossibility of deliberation and due care at the termination of delivery hits at a fundamental error in obstetric practice. He says "of course, one prefers, personally, to clean up all the mess and have done when he has done at the end of labor." A carefully planned operation in gynecology would hardly be described as a "mess," and if the conduct of labor, especially if its course is abnormal and requires operative interference, were carried out on the same lines as other operations "messes" would be less frequent.

One of the commonest errors in obstetric technic is the attempt to do the impossible on a bed, and a more frequent resort to a hard table with more deliberation at the beginning of an obstetric operation will often determine its successful result. The cervix, then, as well as the perineum is best sutured at the completion of the delivery. No particular operation, device or instrument is necessary. It is simply a question of proper exposure of the wound by means of volsellum forceps, sponging, and two, three or four plain catgut stitches. That such wounds can be successfully sutured a day or two later only makes a greater demand upon the attendant, and fortunately allows him time, if necessary, to procure sufficient aid for a successful operation. If a longer delay is necessary they can be treated in a few days, weeks, or even months, but the sooner the better.

The writer, from his own experience, is thoroughly impressed with the excellent results to be obtained from the early treatment of these injuries compared with those usually obtained months and years afterward, when connective tissue changes of more or less permanent nature have occurred. As asepsis in delivery has reduced the morbidity and mortality of the puerperium, so surgery, displacing the hot douche and gauze packing in the puerperium, will still further decrease the number of chronic pelvic diseases.

1736 Broadway.

Annali dell' Instituto Maragliano.—This is the title of a new periodical, just received, to be devoted entirely to the study of tuberculosis and to set forth the results obtained by Maragliano and his pupils in the recently established institute founded for such work at Genoa.

MYELOGENOUS LEUCEMIA WITH DISAPPEARANCE OF THE SPLENOMEGALY AND THE MYELOCYTES.[1][2]

BY CHARLES E. SIMON, M.D.,
AND
D. G. J. CAMPBELL, M.D.
OF BALTIMORE, MD.

Cases of myelogenous leucemia, in which, together with an improvement in the patient's general condition, there is a disappearance of the splenic tumor and at the same time of the myelocytes, are apparently very rare. The only instances recorded in the literature, so far as we have been able to ascertain, are those of McCrae, Senn, Plehn and possibly also one of Kohn.

McCrae's patient was a man, twenty-eight years old in whom symptoms attributable to a leucemia were first observed in the latter part of 1897. The following June the spleen was found to be much enlarged, coming within 2½ inches of the umbilicus. Blood examination at that time showed 45 per cent. of Hb., 2,680,000 red cells and 584,000 leucocytes; of the latter 0.3 per cent. were small mononuclears, 0.6 per cent. large mononuclears and transition forms, 72.0 per cent. polynuclear neutrophiles; 3.0 per cent. eosinophiles and 23.0 per cent. myelocytes. During the count of 600 cells six normoblasts were seen.

The patient was placed on arsenic and general hygienic treatment. The following September the spleen could just be felt on deep inspiration. Blood examination then showed 68 per cent. of Hb. and 4,640,000 red cells, while the leucocytes only numbered 9,250; of these 10 per cent. were small mononuclears, four per cent. large mononuclears and transition forms, 84 per cent. polynuclear neutrophiles and two per cent. eosinophiles. Myelocytes and nucleated red cells were not found.

In November the spleen could be palpated 2.5 cm. below the costal margin. The percentage of Hb. was 67; the red corpuscles numbered 4,160,000, and the leucocytes had risen to 178,000. A relative count showed 2 per cent. of mononuclear leucocytes, 67 per cent. of polynuclear neutrophiles, 9 per cent. doubtful forms (classed by McCrae with the polynuclears), 1 per cent. each of eosinophiles and mast cells, and 20 per cent. of myelocytes. Nucleated red cells had again appeared; 12 normoblasts and 6 intermediate forms between normoblasts and megaloblasts were encountered during a count of 1,000 cells.

By December the spleen had again diminished in size; on the tenth it was found just palpable on deep inspiration. The leucocytes had fallen to 98,000, of which only 8 per cent. were myelocytes. The following April the spleen could not be felt even on the deepest inspiration. The Hb. was 70 per cent.; the red corpuscles numbered 5,328,000 and the leucocytes 5,000. A differential count showed 13 per cent. of small mononuclears;

[1] Presented before the Johns Hopkins Hospital Medical Society February 1, 1904.

[2] Received for publication March 21, 1904.

16 per cent. of large mononuclears; 66 per cent. of polynuclear neutrophiles and 2.0 per cent. of eosinophiles. Myelocytes were not found and nucleated red cells also were absent.

The subsequent history of McCrae's patient is unfortunately not known, beyond the fact that he died suddenly several months later in California, from what his physician regarded as an attack of cerebral hemorrhage.

To summarize, we have here an undoubted case of myelogenous leucemia in whom twice within less than twelve months the classical features of the disease, viz., splenomegaly and myelemia, could be demonstrated and then disappeared. At neither intermission was there any evidence of an intercurrent disease, to account for the improvement.

Senn's case occurred in a woman, aged twenty-nine years. In the early part of the winter of 1902 she first became conscious of increasing weakness and three months later discovered that her abdomen had become greatly enlarged. On admission to Senn's service, January 1, 1903, she was somewhat emaciated and profoundly anemic. The spleen extended nearly to the pubes below and two inches beyond the median line on a level with the umbilicus. Blood examination on February 3 showed 56 per cent. of Hb.; 3,500,000 red cells and 64,800 leucocytes. A differential count is not given. Senn speaks of myelocytes and numerous eosinophiles and also mentions that poikilocytosis was very pronounced.

Following a three weeks' course of iron and Fowler's solution without noticeable improvement, X-ray treatment was instituted on February 3 and continued daily with occasional intermissions until about the middle of June. The spleen presented indications of progressive decrease in its size about three weeks after the beginning of the X-ray treatment, and it was noticed that improvement of the blood condition kept pace with the reduction in the volume of the spleen. During this time high temperatures were observed besides "other symptoms of intoxication." On April 12 the examination of the blood showed no myelocytes and only a very few eosinophiles and very little poikilocytosis; at the last examination which was apparently made in June there were "no abnormalities in the structure and relative number of the red corpuscles and leucocytes."

Senn regards his patient as cured and attributes the result entirely to the prolonged use of the X-ray treatment.

Plehn's case was a male, aged forty years. The patient's complaints began with pains in the left leg on October 20, which rapidly increased in severity and led to his admission to the hospital on October 30. There was then marked tenderness of the patella and the tibia, ascites, hepatic enlargement, icterus, splenomegaly to within two finger breadths of the umbilicus and below this a retroperitoneal hematoma (of splenic origin), slight enlargement of the inguinal and cervical glands, moderate albuminuria and evidence of retinal hemorrhages. The condition of the blood showed a mixed cell leucemia. There was 35 per cent. of Hb.; the red cells numbered 2,180,000 and the leucocytes 90,000, with many neutrophilic myelocytes.

By November 14 the disease had progressed. The spleen extended almost to the umbilicus; new retinal hemorrhages had occurred; the red cells had fallen to 1,600,000 and the leucocytes had increased to 149,000. One third of the latter were myelocytes. From this period there was rapid improvement. On December 8 the albuminuria, the ascites and the hematoma had completely disappeared; the spleen only extended three finger breadths beyond the costal margin. The Hb. was 54; the red cells numbered 3,092,000 and the leucocytes had dropped to 4,600. By the 31st of the same month the spleen could be felt a finger-breadth below the costal border: the Hb. had risen to 60 per cent., the red cells to 3,500,000, while the leucocytes had further diminished to 3,000. This was essentially the condition of the patient at the time of Plehn's report (January 6). The myelocytes had not completely disappeared, but were much diminished—about one to a specimen. Noteworthy is the fact that while the myelocytes represented about one third of the total number of the leucocytes at the height of the disease, the blood gradually assumed somewhat of a lymphatic character, and at the time of the report the mononuclear non-granular elements (comprising both lymphocytes and large mononuclear leucocytes) were present in the ratio of about 45:54.

To sum up, we find that in Plehn's case there had been a drop in the number of the leucocytes from 149,000 to 3,000 in about seven weeks, and that coincidently the splenomegaly had very much diminished. Strictly normal relations had not been established and Plehn himself does not regard his patient as cured; he looks upon the relative lymphocytosis as evidence of a pseudo-leucemia (Ehrlich). The treatment in this case consisted in the hypodermic use of arsenic. Plehn does not refer the manifest improvement in the condition of his patient to its use, however, and suggests the possibility that this may have been dependent upon the resorption of the hematoma.

In the discussion which followed Plehn's report in the Berliner medizinische Gesellschaft, Kohn mentioned two cases of leucemia, which came under his observation and in which an apparent cure had resulted. The data furnished, however, were very meager:

One case occurred in a child, aged three years. The condition here was apparently an acute leucemia (a high grade of anemia and prostration; fever; numerous petechiæ; hemorrhages from the gums, nose and intestines; gingivitis; splenic tumor, enlargement of the liver; slight enlargement of the lymph glands and a high grade of hyperleucocytosis referable to lymphocytes). The condition appears to have been quite desperate, notwithstanding the use of arsenic. This was then discontinued and after a few weeks the child

appeared to be perfectly well again, barring "a certain disproportion of the various forms of leucocytes." The improvement continued for two months. Gradually the liver and spleen become enlarged a second time, the blood condition again became worse, another attack of acute leucemia developed, and the child died.

In the second case the data are too meager to draw any conclusions regarding the condition of the spleen and the blood. The disease had apparently lasted with periods of improvement, interspersed with occasional exacerbations, for ten or eleven years.

Senator further remarks that he has seen remissions in the course of a leucemia which could not be referred to intercurrent disease. He only cites a case of lymphatic leucemia, however, in which the blood was apparently normal, but in which there still existed a moderate enlargement of the spleen. Cases of this order, however, do not enter into consideration in the present instance, as we have reference only to cases of myelogenous leucemia in which, together with an improvement in the patient's general condition, both the splenomegaly and the myelocytes have disappeared. An improvement of either factor alone, irrespective of any intercurrent malady has been repeatedly observed, and to this class of cases the instance cited by Senator and possibly also Kohn's second case belong. There accordingly only remain the three cases of McCrae, Senn and Plehn and the first case of Kohn.[1]

To this small list we can add a further case, wherein both the splenomegaly and myelocythemia disappeared and in which the patient's improvement has now lasted nearly a year.

Mrs. M. S., aged thirty-five years. The patient's family history contains nothing of interest. As a child she had mumps, diphtheria, whooping-cough and malaria; at eighteen measles and at twenty-one pneumonia. Menstruation began at thirteen. She was married twice, the first time at fifteen. From the first marriage she had two children and one miscarriage; from the second two miscarriages. Her general health had been good until 1899. Following a good deal of worry she then lost her appetite and slept badly, but definite symptoms of actual sickness did not appear until two years later, in 1901. She then noticed a bulging from below the ribs on the left side, which gradually increased and extended to the left groin. Coincidently, her dyspeptic symtoms became more troublesome, she suffered from palpitations of the heart on slight exertion, from headaches and also experienced pain below the ribs on the left side, between the shoulder blades and in the legs, which were sufficiently intense to interfere with her sleep. She gradually grew weaker and lost flesh.

The splenic tumor was discovered by a physician in March, 1903, and she was sent to a hospital, where the diagnosis of splenomyelogenous leucemia was made. Her red cells then numbered 1,700,000 and the leucocytes 350,000. She was kept in bed for four weeks and given Fowler's solution in increasing doses.

On April 12, when the patient was first seen by Dr. Simon, she weighed 140 pounds (usual weight 167). She then complained of numbness in her toes and fingers, and had difficulty in fastening her clothes. She looked moderately anemic. The spleen extended almost to the umbilicus and well below the costal border in the nipple line. The liver was not palpable. There was no enlargement of the superficial lymph glands. At the apex there was a soft blowing systolic murmur, scarcely audible at the base, and not transmitted to the axilla; the area of cardiac dulness was not increased.

A blood examination at this time showed 54 per cent. of hemoglobin, 1,760,000 red cells and 4,000 leucocytes. Of these 21.7 per cent. were small mononuclears: 2.7 large mononuclears; 51.6 polynuclear neutrophiles; 6.7 polynuclear eosinophiles; 10.8 mast cells; 5.9 neutrophilic myelocytes and 0.2 per cent. eosinophilic myelocytes. While counting 368 leucocytes, 23 normoblasts and two megaloblasts were seen. Noteworthy was a marked grade of anisocytosis and poikilocytosis, and polychromatophilia also was quite pronounced. Granule cells (red) were present in small numbers.

The patient had been taking eight drops of Fowler's solution three times daily and was instructed to increase the dose.

She was again examined on April 28. She had increased the arsenic to 19 drops three times daily without any untoward effects. Her physical condition was unchanged. The Hb., however, had risen to 67 per cent., and the red cells to 3,400,000. The leucocytes numbered 5,000. A differential count showed 13 per cent. of small mononuclears; 9.3 per cent. of large mononuclears; 60.5 polynuclear neutrophiles; 3.9 polynuclear eosinophiles; 8.5 mast cells; 3.9 neutrophilic myelocytes and 0.5 eosinophilic myelocytes. The nucleated red cells had diminished; only four normoblasts and one megaloblast were seen while counting 352 leucocytes. The plaques seemed much increased. Otherwise the blood condition appeared unchanged.

The next note was made on May 5. The patient had increased her arsenic to 22 drops three times daily, and appeared to be much improved. The physical condition, however, was unchanged. Her weight had increased five pounds and a half since April 12. The Hb. was 68; the red cells numbered 2,112.000 and the leucocytes only 2080. Poikilocytosis was still very pronounced; there were many microcytes, but no tendency to oversize. Granule cells were present in fair numbers. The plaques still appeared increased. While counting 381 leucocytes, only two normoblasts and two megaloblasts were seen. The differential count showed 23.0 per cent. of small mononu-

1 This latter being an acute lymphatic leucemia, with splenomegaly and with slight involvement of the lymph glands only, can probably be regarded as of myelogenous origin and is accordingly included in our list.

clears; 6.3 large mononuclears, 49.8 polynuclear neutrophiles; 7.1 polynuclear eosinophiles; 10.9 mast cells; 1.9 neutrophilic myelocytes and 0.7 eosiniphilic myelocytes.

On May 14 the spleen was found much reduced in size; it could just be palpated at the costal border. Her Hb. had risen to 75 per cent.

During the summer months the patient was not seen. On October 22, when the next note was made, she stated that she had suffered a great deal of pain along the region of the attachment of the diaphragm, and had had an attack of pleurisy, of which nothing definite, however, could be learned. She had taken Fowler's solution with brief intermissions during the entire summer, and had gotten as high as twenty-six drops three times daily. At times she had been very much puffed. Quite recently she had been examined for life insurance and passed. Her weight had increased to 151 pounds. The spleen was barely palpable on deep inspiration. Noteworthy was the marked brownish pigmentation of the abdomen (arsenical). The Hb. was 80; the red cells numbered 4,400,000 and the leucocytes 5,600. Of the latter 29.6 per cent. were small mononuclears, 2.2 per cent. large mononuclears; 55.5 per cent. polynuclear neutrophiles; 4.4 per cent. polynuclear eosinophiles; 5.9 per cent. mast cells; 2.2 per cent. neutrophilic myelocytes and 4.4 per cent. eosinophilic myelocytes.

On November 23 she was again seen. Her weight had increased to 156 pounds, a total gain of 16 pounds since April 12. The pigmentation of the abdomen remained unchanged. The spleen could scarcely be felt. The patient had been taking her arsenic quite regularly—up to 26 drops three times daily, but has had a good deal of digestive disturbance. There is still pain along the lower ribs on both sides. The Hb. was 75; the leucocytes numbered 5,000. Of these 19.8 per cent. were small mononuclears; 6.2 per cent. large mononuclears; 62.7 per cent. polynuclear neutrophiles; 1.8 per cent. polynuclear eosinophiles; 6.8 per cent. mast cells; 2.4 per cent. neutrophilic myelocytes.

December 16. The patient has still maintained her high doses of Fowler's solution—26 drops three times daily—with brief intermissions. There has been some nausea, which improved on withdrawal of the arsenic. The pain along the lower ribs and between the shoulders is frequently quite distressing. The spleen is scarcely to be felt. The leucocytes numbered 4,000.

On January 26 the patient's physical condition was still unchanged, but she is manifestly not standing her arsenic so well as formerly; with the higher doses, 20 to 26 drops three times daily, she has a good deal of nausea and has vomited on several occasions. The pain between the shoulders and along the lower ribs continues as before—at times better, at times worse.[1]

Her headaches, from which she suffered quite frequently early in the course of the disease are much improved; she feels stronger in every respect and is no longer troubled by palpitation of the heart. Her weight is 152 pounds. She looks well and certainly does not make the impression of an invalid. The pigmentation of the abdomen is very marked, especially in the flanks; the elbows also are quite dark. The spleen can just be felt on deep inspiration; this is greatly facilitated by the relaxed condition of the abdominal walls and the wide costal angle without which the organ could probably not be palpated at all. The lymph glands are nowhere enlarged. The Hb. is 76 per cent.; the red cells number 3,984,000 and the leucocytes 4,500. There is still marked poikilocytosis and some anisocytosis. The small mononuclears were 34.0 per cent; the large mononuclears 31 per cent.; the polynuclear eosinophiles 6.3 per cent.; and the mast cells 11.5 per cent. Myelocytes were not found in a count of 1,000 cells. Nucleated red corpuscles were also not encountered.

The last examination was made on March 8, *i.e.*, just about one year from the time when the patient first went to the hospital. For the first three weeks following the last note she had taken no arsenic whatever; since then she has resumed her drops, but has not been able to get beyond ten drops three times daily; even this amount is not so well borne, but causes a great deal of nausea. She has gained three pounds, and looks quite well. The condition of the spleen is as above. The Hb. was 80; the red cells numbered 5,200,000 and the leucocytes 6,500. Of these 26.7 per cent. are small mononuclears; 14.4 per cent. large mononuclears; 51.5 per cent. polynuclear neutrophiles; 3.3 per cent. eosinophiles and 3.5 per cent. mast cells. An occasional myelocyte was encountered, but the number did not exceed 0.4 per cent. There are a few granule cells. The poikilocytosis is much improved.

To sum up, we have a patient in whom three years ago undoubted symptoms of a myelogenous leucemia developed. When the patient entered the hospital one year ago her spleen was greatly enlarged and the blood was absolutely characteristic of the disease, the leucocytes numbering 350,000. A month later they had fallen to 4,000; the myelocytes had diminished to 6.1 per cent. and there was nothing in the blood picture with the exception of the high percentage of mast cells (10.8) to suggest a leucemia. The spleen, however, was still quite large. Six weeks later this symptom also had nearly disappeared and ever since (now ten months) the spleen has been scarcely palpable. The patient's weight has increased; her Hb. has risen to over 75 per cent. and the red cells have increased correspondingly; the number of the leucocytes has been normal and even subnormal; and at no time since April 28, 1903, has the percentage of myelocytes been above 2.4; on January 26 indeed not one myelocyte was seen in a count of 1,000 cells. Significant, however, is the fact that the mast cells

[1] The persistent character of this pain, while not uncommon in leucemia, led to a careful examination of the urine. The Bence Jones' albumin was absent.

have been constantly much above the maximum normal; they varied between 3.5 and 10.8 per cent. As is well known, Ehrlich has laid great stress upon this factor in the diagnosis of myelogenous leucemia, and there is indeed no other condition known in which a similar increase has been observed.

Senn and Plehn unfortunately have published no differential counts in their cases, and McCrae only gives one mast cell count, which was made during an active period of his patient's illness.

Upon the basis of the greatly increased percentage of mast cells we believe that even now, and without a knowledge of our patient's past history, the diagnosis of myelogenous leucemia would be justifiable. Notwithstanding the general improvement, the disappearance of the splenomegaly and the absence of myelocythemia, there can scarcely be any doubt that the arrest of the disease is merely temporary, if indeed there is arrest of the pathological process. Opposed to such an assumption is the fact that even now there is a certain degree of poikilocytosis, which is out of proportion to the degree of residual anemia. This feature has been quite remarkable ever since the patient first came under observation, and together with the occasional increase of the color index was strongly suggestive of a pernicious anemia. That the blood picture of leucemia may pass over into that of pernicious anemia has been observed. Gerhardt[6] thus recorded a remarkable instance where the ratio of the leucocytes to the red cells had been 1.3; the leucocytes then rapidly diminished within three days, and the blood picture of the leucemia was replaced by that of a pernicious anemia. In our case there was lacking, however, that grade of granular degeneration of the red cells, which in pernicious anemia is so marked and so constant; besides, the small mononuclear leucocytes were not increased, while in pernicious anemia during the active stage of the process this is a very common event and to a certain extent characteristic. The significance of the increase of the mononuclear elements, which has been noticeable of late, can only be a matter of speculation.

As we have already stated, we do not in the least believe that our patient has recovered, nor do we think that Senn has adduced sufficient proof to warrant the conclusion that his patient was cured. This patient was dismissed from observation about the middle of June—3½ months approximately after the spleen first showed signs of diminution in size. Senn's article appeared on August 22. This interval is certainly too brief to warrant any fargoing conclusions, so far as the question of a cure is concerned. In the light of our own case, and that of Plehn, moreover, it scarcely seems justifiable to refer the improvement in the patient's condition to the use of the X-rays. Whether it would be admissible, on the other hand, to ascribe the improvement in our case and that of Plehn to the arsenic may similarly be questioned. The treatment in Kohn's case is not very clear, but it seems that the improvement began when the arsenic was discontinued. We believe these cases merely show that both the splenomegaly and myelocythemia may temporarily disappear, together with an improvement of the patient's general condition, but the rapid recurrence in Kohn's first case and in McCrae's patient, and the death of both, throws grave doubts upon the propriety of viewing such improvements in the light of a cure.

Since the above notes were sent to the editor several additional examinations were made of the patient's blood, the last on the 23d of May. Her red cells then numbered 5,480,000 and the leucocytes 3789. There were 47 per cent. of mononuclear elements, 35 per cent. of polynuclear neutrophiles, 6 per cent. of eosinophiles and 12 per cent. of mast cells. There were no myelocytes and the poikilocytosis and anisocytosis had almost entirely disappeared. The patient's general condition remained unchanged, and the spleen was not palpable even on deep inspiration. The improvement has thus continued for over a year.

In the literature three additional cases have been recorded, in which a symptomatic cure was apparently effected. The interval in these cases which has elapsed between the return to approximately normal conditions and the time of publication, however, is too brief to warrant any fargoing conclusions. The cases in question are those of Brown[7], and Bryant and Crane[8]. In two of the three the improvement may have been referable to the X-ray treatment, which was employed, but in Bryant and Crane's second case arsenic only was used. It is interesting to note that in this case there was a hematoma of the right ankle, the result of an injury, which was incised on two occasions.

A fourth case of myelogenous leucaemia has further been reported by Grosh and Stone, in which, as the result of X-ray treatment apparently, there was a marked improvement in the condition of the blood, but in which the splenomegaly did not disappear. The number of the leucocytes in this case fell from 266,250 to 10,600 and the myelocytes from 52 to 2 per cent., while the patient's general condition also was improved. This patient rather suddenly, i.e., within a few days, began to fail in strength and died of general asthenia.

In reference to Senn's case finally I have a note written in April, according to which the patient then had a mild relapse. S.

A VISIT TO GHEEL.

BY SMITH ELY JELLIFFE, M.D.,
OF NEW YORK;
VISITING NEUROLOGIST, CITY HOSPITAL; CLINICAL ASSISTANT, DEPARTMENT OF NERVOUS DISEASES, COLUMBIA UNIVERSITY.

To one who has been accustomed to approach the dwellings of the insane as one would a king's palace; to proceed through avenues and formal gates to an imposing edifice, and to be ushered in by attendants to the presence of the superintendent of an American hospital for the insane, it was something of a novelty to arrive on a local train in the late evening at the small station of Gheel, in Belgium, and to be suddenly set down in the dark in the midst of a colony of nearly 2,000 insane people who were living at large in any or perhaps all of the cottages that were faintly discernible in the dusk of the flat landscape.

No vehicle or porter and no sign of life was visible in the town, except a few lights in the village. A bowing acquaintance with scientific German and French is of but slight aid when one is twenty-five miles from the linguistic center of Antwerp. Flemish was the only tongue of the natives, but the presence of a valise and the ignorance of the language plainly indicated the necessity of a hotel, and we were soon being guided by a taciturn fellow through the one long, closely built street, to the only hotel of the village. Side by side, and level with the street, without doorstep or garden plot or outside walk, the low two-storied houses made an unbroken wall on either side of the street. Shuttered windows and the wide deserted street gave the impression, which was probably true, that at eight o'clock the business and social life of Gheel was at an end for the day.

Visitors for Dr. Peters, the Director of the

VIEW OF GHEEL. CHURCH OF ST. DYMPHNA.

Colony at Gheel, were evidently a proper source of revenue to the inn, and despite the extreme lateness of the hour our guide, whom we found was an epileptic, was bidden to take a note announcing our visit to Dr. Peters the next morning.

To obtain a carriage for the tour we wished to make seemed a proper courtesy, for we learned that there was no livery connected with the institution, and that the physicians and assistants made their visits over a space of nearly twenty square miles by bicycle, or by means of a local train, or on foot. No carriage was to be had, however, in Gheel, everything that horse could draw was in requisition for a pilgrimage to some shrine in a neighboring village. This reminded us that for centuries Gheel had had a shrine to which pilgrims came to be cured. In the ninth century a young Flemish girl had been beheaded there by her father, who was enraged because she repulsed his amours. In the early days sufferers from all diseases came to be cured at her tomb, which gradually became famous as a resort for "those possessed of evil spirits." In fact, the actual origin of the system of boarding out patients which now constitutes the colony, was in part due

A STREET IN GHEEL.

to the fact that the pilgrims could not all be cared for by the church, and the inhabitants of the town offered their hospitality to the strangers until such time that their turn might come for the miracle to be invoked in their behalf.

For many hundred years the treatment of the insane at Gheel consisted only in prayers and penances and exorcisms; in the eighteenth century the colony became a recognized local institution; but it was not until 1851 that the State assumed control over it and regulated its affairs.

Since then the colony system for the care of the insane has been brought within the jurisdiction of the Minister of Justice, and is subject to the various laws which control all the institutions for the insane in the kingdom of Belgium.

By reason, however, of its slow growth, and the personal interest of its directors, a very interesting economic and social condition is presented by the existence of the colony. Had Gheel been organized on paper before the colony came into existence, it would have been laid out straight, plumbed and drained, and the cost of maintenance would have been greater to the State. As it is, it consists of a poor rural community, small farms, occupied by low one-story dwellings, tiny villages, with the town of Gheel at their center, and meadow lands traversed recently by local steam cars, run much on the principle of an American trolley.[1]

The only imposing buildings in the town other than the Cathedral, which rises from the market-place, are the administration buildings and infirmary of the Colony of Gheel. The double row of fine trees and the shrubbery and grass at

[1] (See article by P. Masoin, "Care of the Insane in Belgium." *Journal of Nervous and Mental Disease, August-September*, 1904 (in press).

the entrance lent dignity to the buildings which would have been considered small for administering a colony of this size in America. But within, the strictest economy of space was observed. The large, home-like living room of the superintenent, Dr. Peters, served as a reception room which led

AVENUE OF THE INFIRMARY. DIRECTOR'S OFFICE TO RIGHT.

immediately to plainly furnished business rooms and thence to the wards where a few sick patients were being cared for, and a small number of semi-private rooms where certain patients always lived. About sixty can be accommodated here, if for bodily or mental ailments they must be removed from the homes of their guardians.

The small garden in the immediate rear was brilliant with flowers, and rich in fruit, plums, grapes and pears hanging thick on low carefully trained trees and vines. The barred windows of the detention rooms, where newcomers spend their first few nights, or where violent cases are watched, looked out on a level with the garden; and on stepping from one part to another there was a sense of cosy compactness and consideration for the home comfort of every one dwelling within the grounds.

At the hour of nine, when we arrived, Dr. Peters, the Medical Director, who is at the same time chief of the administrative as well as the medical service, was busy receiving the reports of his assistants on their preceding day's work.

From a medical point of view, the colony is divided into four sections, each of which is cared for by a physician who has two section guards to help him. These physicians must devote themselves exclusively to the care of the insane, and are formally forbidden to practice, except in matters of expert medicolegal work. They must visit the curable patients once a week and the others once a month. At each visit the physician signs a card which the patient's guardian keeps, recording the condition of the patient's room, general care and condition. The section guards see that the physician's special orders are carried out, and report each evening to his superior. After each physician has made a morning's report of his own and his assistant's work, the Medical Director finds himself in close touch with all the work of the Colony.

At a first glance it would seem as though considerable time must be lost daily in going from house to house, and it is true that the distances which must be traversed take considerable time, as some patients live several miles from the administration building. As the placing of patients in families is decided by a local committee in the town, and does not rest wholly with the Medical Director, there is some friction caused by the fact that patients are not grouped as conveniently as they might be, and are not always placed in surroundings suitable to their cases. But this limitation of the Director's power seems to be the only one that causes any trouble in the harmonious and wise administration of the colony.

The physicians travel from house to house chiefly by bicycle, covering long distances by the local train. The ease with which a physician can care for a ward full of patients in an institution as compared with the slow personal visiting is at first sight a factor in favor of the institution system, but when it is remembered that four men and eight deputies attend systematically to over 2,000 patients, and that no paid attendants are employed, it will be seen that the system is arranged much more economically than in our institutions, and that the only persons who might have

THE INFIRMARY AT GHEEL.

reason to complain are the hard-working young physicians themselves, who, on salaries as proportionately modest as are all the other expenses of Gheel, nevertheless do very excellent routine work, as well as original investigation.

The personal interest and oversight of the Medical Director was apparent within the first quarter of an hour's tour of the infirmary with Dr. Peters. The spotless condition of the bare floors, windows and plain furniture and bedding indicated a cleanliness arising from work which lent an impression of thrift and good management that one does not get in a modern tiled and plumbed institution of America. In a large and cheerful sitting room a few patients were gathered, who, though possessed of means sufficient for a private institution, had been sent to Gheel for the benefit of family life, and were on account of their greater refinement, lodged more nearly under Dr. Peter's care; but with the exception of a few who had been suffering from a period of disturbance, or slight accident, and a few aged patients who were nearing the end, the Infirmary was not occupied; for the class of patients who are sent to Gheel are such as require but little hospital care.

As a rule they are all able-bodied and are taken largely from rural homes where their presence is

a hindrance to the other members of their families, and are transferred to the homes of Gheel where their slight services combined with their board make them a welcome addition to a poor community. No patients are admitted to the colony who must continually be kept under restraint, nor who would offend public decency; and none who have homicidal, suicidal or incendiary tendencies.

All who are able to work are paid a small sum each week by their nurses or hosts. Some work in the field, others in the shops, while the women tend children, prepare vegetables and do household work.

According to their value as workers or to the care they require as patients, the sum paid to their nurses for their board by the state varies. In our land of luxuries it is impossible to believe how little is required for the per capita maintenance of the patients on this system.

Paupers who are able to work and who are quiet and orderly, belong to the first class. For them 64 centimes, or about 12 1-2 cents is paid daily for board. In this class are a good many idiots and dements. For paupers of the second class, those who are noisy or semi-depraved, 80 centimes, or 16 cents a day is paid. Patients of the third class, wholly depraved or epileptic, bring with greater care the larger revenue of one franc, five centimes, or 21 cents a day, to their nurses.

Patients whose friends have means can be lodged with more comforts at a higher rate in the

TYPE OF HOUSE IN WHICH PATIENTS ARE QUARTERED.

homes of the more well-to-do. For, through the long establishment of the custom, the permission to have patients is largely sought as a favor by nearly all the householders of Gheel.

It was with these statistics in mind that we started forth with Dr. Masoin, one of the attending physicians, to make his daily rounds. Our institutionized proclivities demanded a carriage in order to see the most in the shortest time, but there appeared to be no coach and pair even at the bidding of the superintendent, and our efforts to engage any kind of a conveyance in Gheel proved fruitless. The pilgrimage to the shrine in a neighboring village was still a drawing attraction, and every horse had jogged off with a load in the early morning so we were obliged to make a typical day's rounds in the usual fashion.

A ten minutes' ride in the railway train brought us to a little hamlet of half a dozen cottages, farms and a few houses near each other in the road. These latter seemed to bear a commercial relation to the others. In one bread and ginger-cookies were sold. A woman came into the bare front room where the counter was, with several children clinging to her skirts. Through the open door we could see in the clean little back court beyond the "big child," a dull-looking imbecile, who was slowly peeling potatoes, and around whom the children immediately went to play, as soon as we had bought out the stock of one of their mother's candy jars for them.

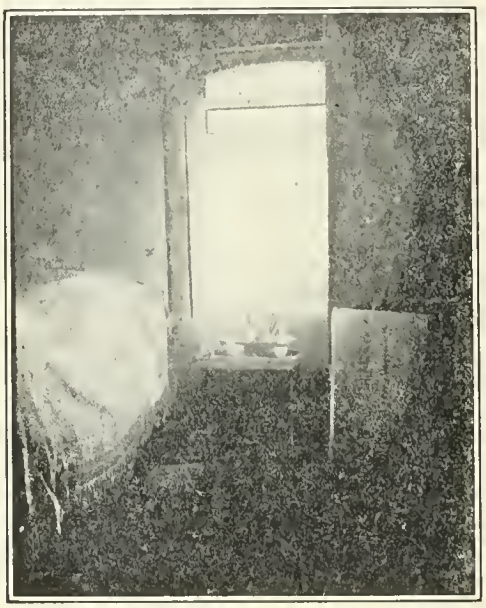
In the next house, a few deal tables and the presence of the man of the house and several others eating bread and cheese, indicated a tavern. A sleek, melancholy looking man of thirty, with a child-like smile, was the patient. He was afflicted at times with religious mania, and his guardian, the tavern keeper, explained in detail, and with considerable intelligence, their boarder's condition for some days past, his silence and troubled stare and continual praying, which he feared was the preliminary of an attack. The neighbors listened with interest and the patient sat among them brooding in his corner, in the attitude of one who is aware of sympathy rather than of being shunned. In his rooms were several religious pictures and adornments, as well as family photographs. These showed his family group, of evidently well-to-do tradespeople sitting on the porch of a suburban home. He wrote to them and received their letters, but seemed to be perfectly content in the less conventional surroundings of friendly farmers.

In a third house which we entered we found a picturesque interior belonging to the type of low thatched farmhouse, which is now giving way to the slated brick house. In this an enormous crane in a huge fireplace supported a great iron pot, in which over a tiny fire, a mash was being prepared for the cattle. When it was ready the kettle was swung round to a low door beside the fireplace that entered directly into the stable, and there tipped up, without being taken from the crane in the living room, the mash was poured directly into the trough of the cows, who had their heads well within the door in their expectation.

A little old dame of eighty years was the guardian in this home. Her short petticoat and wooden shoes, the sanded floor with its combed pattern, the little white curtains and pots of flowers in the windows, and the row of bright pewter plates on the dresser, all had a flavor of a faraway time, that this prosperity of 21 cents a day income was fast driving out of Gheel. She brought out her patient with the pride of a grandmother. He was a clean, palsied, smiling old fellow of seventy, whom she and her husband had cared for for fifty years in this home. His shaking fingers were covered with brass and wooden

rings over the knuckles. These he played with and held them up sheepishly for inspection. His guardian told us indulgently that he had a sweetheart and was engaged to be married to her, and patted him as she would a child, at which the old fellow nodded and laughed and mumbled garrulously.

This was a prize household, for on the walls were several little plainly framed cards certifying that once and again she and her husband had won one of the money prizes, which are graded up to twenty-five francs, for the best personal care of their patients and the most neatly kept rooms and house.



A PATIENT'S ROOM.

In every case the physician went into the patient's bedroom, ripped open the bed, and saw that its course sheet and woolen blanket were clean, examined the additional garments hanging on the wall, and entered his report on the card which the guardian brought to him as he entered. In all cases the tiny bedrooms were scrupulously clean and the bare floor sanded. They were generally on the first floor and opening directly off the living room. In many of the more modern houses they are built expressly for the patients and supplied with a regulation style of bed and bedding. The doctor included in his inspection the food of the household, the back yard, which seemed to be the family gathering place and workroom, and the patient's personal appearance. The card was checked with his visit. A system of card checks is used for the visits of both the physicians and the attendants. These are subjected to directoral supervision at stated intervals. Such supervision is far from perfunctory.

The food of the patients is the same as that of their guardians, and consists of vegetables, potatoes, salt pork, milk and bread and butter. Very little fresh meat is used, and then generally as a stew. Much of the bread is of rye. The patients eat at the table with their guardians, and as there are never more than two in a family, they are absorbed and made part of the family life. More than that number would make a separate faction in the family. Although the food is not of a high grade, it is the food of the peasant class to which most of the patients belong; so it is quite as good as they would get in their own homes.

NEW BATH-HOUSES FOR THE COLONY.

The guardians are obliged to feed their patients as well their payments will permit, and a sort of check is kept upon them by means of the bath-house weighing system. In several parts of the community have been erected neat bath-houses to which patients are taken in detachments each week. Once a month each patient must be weighed, and if the weight falls short at any time except in the summer months, when a certain loss is expected, the guardians are held accountable for his food. Unquestionably the diet is poorer than in our institutions, but it is evidently sufficient, and a system of inspection among the deputies who may happen in at any meal to examine the fare, tends to stimulate the housekeeper to make the most of her rather restricted means.

Many features of medical and economic interest were for a time lost in the charm of the unique surroundings of this Colony of Gheel. Innumerable questions arose, to be forgotten in the quaintness of the landscape and the picturesqueness of the people, their houses, and their thrift and their poverty.

It seemed so different a people and so far away a time that comparisons for our own peoples, and our own times appeared impossible. What has been built up at Gheel through centuries cannot be suddenly reproduced here in America. The idea is being developed, as we all know, in several communities in different States, but we can never hope to build up artificially a system which in its most essential features can resemble Gheel. Could we find here and there a simple kindly farming community discouraged by the stern laws of supply and demand, and imbue the inhabitants with a combined spirit of philanthropy and commercialism, we might gradually with great tact find homes for many thousands of our insane, in the course of the next fifty years.

64 West Fifty-Sixth Street.

PERSONAL EXPERIENCE IN THE TREATMENT OF TYPHOID FEVER.[1] [2]

BY CARTER S. COLE, M.D.,

OF NEW YORK.

ALL of us who have had any considerable experience in any direction are prone to believe, either correctly or incorrectly, that we have found some way to meet the problems offered, which is easier for us (and as safe for our patients) than any with which we have become familiar from the literature. Or, it may be fairer to say that our experience has been crystallized so as to offer in a way that is the result of reading and experience something that is in effect the same, but is in reality different. In short, our individuality must be impressed upon our work, and it is with this understanding that I presume to give you a short review of my own experience in treating a disease all too common and, alas, too frequently fatal.

As far back as 1887, when in the Charity Hospital (Blackwell's Island) I carefully reviewed the subject in many authorities, and in a lecture given to the nurses there the following year, I stated as my belief that the nurse who was fitted to care properly for a case of typhoid fever needed no other testimonial to her ability in her profession.

Fifteen added years of experience with that disease have amply justified this statement, and I might add that the physician who is abreast of every possibility in that disease is well equipped to care for a large portion of the ills of mankind.

To fairly fix a plan of treatment in any disease it seems to me quite necessary to be agreed on the etiology and pathology of the same; and, fortunately, in typhoid fever, this is settled with sufficient security to enable us to draw some warranted inferences as to what we must expect and how far we can hope to influence what we find.

The existence of temperature is a necessity, is a part of the disease, and its control is our important mission; the state of ulceration, the character of the typhoid poison in the individual case and its effect on the patient are our guide posts as to what is a normal increase of temperature in the case under our care. In short, every case of typhoid has its own peculiarities which must be noted, and carefully considered in carrying out the treatment for that case. This is true not only in regard to temperature variation, but also as to the nutrition, intestinal condition, nervous condition, tongue conditions, etc.

I could illustrate indefinitely, but one or two instances will be sufficient to emphasize my meaning. Two gentlemen in general about the same age, size and vitality, contract typhoid from apparently the same source and at the same time. One has a high-fever type, with an eruption from his neck to his feet. The other never has a temperature over 100° F., and a very limited abdominal rash. The one is delirious all the time and dies of heart failure at the beginning of the fifth week; the other is never delirious but has almost a melancholia, from which he does not recover for nearly a year.

Again, a child has a frightful attack of typhoid of the high-fever type, characterized by a profuse eruption, accompanied by a pneumonia in the original attack and by an infection of the large intestine in the relapse. One of her nurses contracts the disease and has a comparatively simple attack with few spots, with low temperature, and only troublesome on account of the great difficulty in keeping her sufficiently nourished by reason of an ever-present nausea.

The first is fatal, the second makes a good recovery, interrupted only by return of temperature due to interference with intestinal secretions and to a lack of nutrition, owing to the difficulty mentioned.

And, let me here remark the frequency of this form of recrudescence, often wrongly attributed to reinfection, the error being especially serious to the patient, as the treatment of the two conditions is absolutely different. In cases of relapse the same treatment must be pursued: in recrudescence due to low vitality and not to reinfection solid food must be added and the nutrition generally improved. I might indefinitely parallel cases, apparently due to the same infection, but absolutely different in their type and in many manifestations.

We all know that the high-fever type in the first week does not necessarily mean high-fever type for the whole attack, and we know too well the false security that the early low type of fever is apt to engender. Perhaps it is fair to say in a general way that 101° F. is the average fever type for the first week; 102° F. that of the second week; and 103° F. that of the third week, and basing my belief upon this generalization, admitting that higher, and less frequently lower types are by no means uncommon, I have for years systematized my baths and my stimulation, using the actual fever in the individual case as my guide.

The same is true in regard to nutrition. Some cases need much more nutrition than others; some get along better with a limited amount of nutrition. All cases in my experience do best on an absolutely liquid diet during the fever period.

In planning then the treatment of the typhoid case, we must consider: First, the nutrition; second, the stimulation; third, medication; fourth, antipyresis.

On the question of nutrition there is a fair degree of unanimity, except as to detail. Peptonized milk and koumyss have been my general sources of reliance for nutrition, and with slight variations for the individual case, I order six ounces every two hours between 6 a. m. and 12 midnight, with a single feeding usually between 12 midnight and 6 a. m. Sometimes I make the interval three hours and seldom find cases in which I am unable to give 48 to 50 ounces of

[1] Read before the Alumni of the Charity City Hospital Wednesday, March, 1904.

[2] Received for publication April 8, 1904.

liquid nutrition in the twenty-four hours. Water I allow *ad libitum* throughout the disease.

When I find that milk in any form is not well borne I employ some of the beef, mutton, chicken, clam or oyster broths, the white of egg and sometimes the yolk of one or two eggs, always recognizing the fact that when we are unable to use milk for nutrition the troubles for our patient and ourselves are multiplied.

Next we consider the subject of stimulation, and on this point there is considerable difference of opinion; my own preference is for good whisky in one-half ounce doses where it is well borne and does not cause an increase in the pulse but seems to steady and strengthen it, given after each bath, or if it cannot be taken so often, at least four times in the twenty-four hours. Some patients cannot take any form of alcohol, but those that can are more easily furnished with something for combustion which will save the tissues and conserve the strength. In fact, in my experience alcohol has been quite as valuable for food as for stimulation. The cases which cannot take whisky will sometimes take brandy very well, the dose being a little less; occasionally champagne can be used to advantage. Other wines have not proved very valuable in my hands.

The question of cardiac stimulation has been readily solved for me by the use of nitroglycerin and strychnine in the cases in which it seemed to be indicated. I have found it necessary occasionally to begin the use of these drugs almost at the outset and continue into the period of convalescence. In several cases I have found that they were not required at all. In the majority of cases I find that the use of 1-100th of a grain of nitroglycerin and 1-50th of strychnine from two to four times in the twenty-four hours, beginning about the tenth or twelfth day, and keeping up the administration into the convalescent week, seems to give the heart useful stimulation and support. Where the strychnine seems to increase the nervous and muscular irritability, we must substitute some other form of heart stimulant. Strophanthus is useful, and in some cases digitalis seems to be of benefit, but my preference is always for the first named drug.

The third on the list is medication and can be very easily disposed of. Aside from meeting special indications I may say that I use no drugs at all. At the outset I like to get the intestinal canal thoroughly cleansed, usually by a dose of calomel followed by a saline cathartic; after this I seldom if ever find it necessary to use any catharsis at all, the bowels being moved either daily or every other day by the use of a simple enema.

In cases in which hemorrhage threatens, or is present, I find the treatment employed for many years by Dr. Pepper of Philadelphia entirely efficacious, viz., one-sixth grain of nitrate of silver given every three, four or six hours, or even as often as every two hours in individual cases. I have not found it necessary to follow his practice in giving it in all cases from the beginning of the second week to the end of the third week, but I have not hesitated to do so in the high fever type, where considerable intestinal disturbance seems to threaten. I have not found that adrenalin acts as well as the nitrate of silver. In cases in which there is much diarrhea I use a powder of pepsin five grains, bismuth subnitrate fifteen grains, soda bicarbonate fifteen grains and powdered opium one-sixth grain, and repeat this powder after every second movement. I do not recall ever having used the powder more than twice in twenty-four hours or more than one-half dozen times in the same patient. Abdominal distention has been a rare exception in my cases, but when it has been present has seemed readily to yield to the use of turpentine stupes externally and ten to fifteen drops of spirits of turpentine internally, three or four times in twenty-four hours. In convalescence, and sometimes even in the third week of the disease, quinine in 5-gr. doses twice or even three times in the twenty-four hours seems to act as a good tonic. More especially is this true in cases which have previously had a distinct malarial history.

On the question of antipyresis there is much to be said, and yet I believe that the experience of those who have had most to do with typhoid fever is fairly unanimous in support of the proposition that the coal-tar products used with any degree of frequency do more harm to the heart muscle than would the temperature. It is comparatively easy to reduce the temperature by any of the many coal-tar products, but it is not so easy to restore tone to the heart muscle and to the intracardiac ganglia after they have been assailed by such cardiac depressants. Consequently I may say that practically I never use the coal-tar products in the reduction of temperature; and while we do not always, by either the tub bath or the sponge make any material change in the temperature, in fact, frequently a slight rise will follow the bath, although this is later followed by a fall in temperature, we do make a decidedly favorable impression upon the nervous system and upon the skin, we do furnish added water for the system to consume, with increased elimination of waste products both by the skin and by the kidneys, and do in a measure hold in check the advance of temperature.

My experience with the Brandt method has not been as satisfactory as with sponging. There are many reasons for this. Some patients are much disturbed by being lifted out of bed into the tub, others are quite as much disturbed even where the tub is made in the bed itself. Some patients cannot even stand cold sponging, and in this case we are forced to use the tepid sponge. Indeed, in many cases the tepid sponging seems to be as efficacious as any other kind, although in high temperature cold sponging is much to be desired, and where well borne seems to give much better results.

Returning to our original proposition that fever is a necessary part of the disease and that a certain type in a general way characterizes the dis-

ease in the first, second, and third weeks, we have upon this presumption for a number of years reduced our sponging to a matter of system which can be very easily presented in a few words.

For temperatures up to and under 102° F., tepid sponging twice a day; up to and under 103° F., tepid or cold sponging three or four times a day. Up to and under 104° F., four times a day, and over 105° F., every two or three hours.

I may add here that when I use whisky I give it after the bath, not before. In the individual case I may use whisky less frequently, and in children when I use it at all I do so in one or two teaspoonful doses.

In the treatment of the complications we must follow the lines indicated by our own experience, remembering that we have the typhoid poisons to deal with in addition to the complication itself. In one case that I recall a very severe pleurisy came on during convalescence when the patient was almost ready to leave the hospital, the pleuritic fluid giving always the Widal reaction. The pleurisy gave us more trouble than the typhoid, but eventually the patient made an excellent recovery. In this case a withdrawal of a considerable quantity of the fluid was necessary for the patient's comfort, but in another case if we found that we could make any impression upon the pleurisy without the use of the aspirator we should not be inclined to enter the chest cavity.

I am not, however, inclined to take up the question of complications, as it is an entirely independent subject.

In conclusion, we can thus summarize:

First—Fever is a necessary part of the disease and varies according to the week in which it occurs.

Second—We cannot change the type although we may control the fever.

Third—The use of coal-tar products for the reduction of temperature is seldom if ever desirable, but the use of water externally and internally is a necessary part of the treatment of the disease.

Fourth—Nutrition must be liquid and must be adapted to the individual case.

Lastly, medication plays a very small part in the management of the disease and is only used to meet special indications.

EXTRAUTERINE PREGNANCY—SOME OBSERVATIONS IN A CASE RUPTURED BY EXAMINATION.[1]

BY W. L. WALLACE, M.D.,

OF SYRACUSE, N. Y.

PRIMARY extrauterine pregnancy is classified according to its location in the tube. The common variety is situated in the dilated outer portion and is called *ampullar*. Much less common is the *isthmial* variety, situated in the narrow inner portion, near the uterus. A third variety occurs in the portion of the tube passing through the substance of the uterus, and is therefore called *interstitial*. If the extrauterine pregnancy changes its position or condition by rupture or further development, it is called a secondary extrauterine pregnancy; thus, following the ampullar and isthmial varieties, we have the tubal mole and tubal abortion, the tubo-abdominal or abdominal, and the intraligamentary varieties.

Kelly had 23 cases of extrauterine pregnancy in 1,000 celiotomies reported in 1898, and others have reported a higher ratio. In 300 celiotomies, I have had nine cases, as follows: One double ampullar, ruptured on right and unruptured on the left side; three ampullar, ruptured; one ampullar, unruptured; two tubo-abdominal, probably secondary to ampullar; one isthmial, ruptured; one interstitial.

The interstitial variety is rare, Martin observing only one case in seventy-eight. It is situated in the cornu of the uterus, overlapped by the round ligament; and the abdominal portions of the tube are not involved. It may push into the uterus and continue as a uterine pregnancy, in which case a large portion of the placenta may be left in the tube, complicating labor; or it may rupture into the broad ligament or the abdomen. According to Kelly, this variety is peculiarly liable to rupture, and the hemorrhage is generally rapidly fatal.

The following case of interstitial pregnancy was fortunate in having the rupture occur in the hospital with the operating room ready and assistance at hand:

Case I.—Mrs. D., aged twenty-four years. First seen January 5, 1904. *History.*—One child, three years old, one child thirteen months old, which had nursed until seven months old, August, 1903, when the mother's breasts had dried up. The patient menstruated regularly from the second month, the last time, October 30, when the baby was ten months old; no blood or other discharge since. December 1 she passed over menstrual time, had much nausea, thought herself pregnant; had occasional pains after December 1. Christmas day had quite hard pain for a short time, no tenderness. December 28, 5 P.M., sudden pain, severe, located around the navel, lasted all night, no faintness, patient screamed. A doctor was called, but could find nothing, and concluded that an abortion was threatened. Patient was confined to bed one week by pain and tenderness, but gradually improved. No chill, and no bladder or bowel symptoms. January 5, the patient had been up around the house two or three days; at 3 A.M. was awakened by severe pain which lasted one hour and was again severe at 7 A.M., and hard all day.

Examination.—I saw the case at 8 P.M. January 5, 1904, in consultation with Dr. Chaffee. The pallor was striking, so that the first thought was, hemorrhage from extrauterine pregnancy: but any prejudice in this direction was dispelled by finding pulse 80, temperature 98.2° F. The abdomen was not distended and not very tender. A watery discharge was squeezed from the nipples. No vaginal discharge. The uterus was very low,

[1] Received for publication April 9, 1904.

cul-de-sac bulging and very tender. I could feel no mass, and the extreme tenderness fortunately prevented any satisfactory examination.

Diagnosis.—Probable extrauterine pregnancy, in spite of the fact that there had been no irregular bloody vaginal discharge. The patient was sent at once to the Good Shepherd Hospital, in an ambulance, at 9 P.M., for further observation.

January 6, temperature 99° to 100° F., pulse 80 to 90. Leucocyte count 10,400. Considerable pain and much tenderness. January 7, condition the same, and the patient was therefore taken to the operating room at 9.15 A.M. for examination under ether. The uterus was retroverted and at the left and enlarged to the size of a four to six weeks' pregnancy; no mass could be felt at the side or posteriorly. I replaced the uterus easily, and not finding a mass concluded that we were dealing with an incarcerated pregnant uterus and threatened abortion. 9.30 A.M., patient left operating room, pulse 120. 9.45 A.M., I was called. Pulse was 180, patient perfectly conscious, recovered from anesthetic. 9.50 A.M., I watched the case five minutes while the operating room was being prepared. The pulse dropped to 140 and therefore I waited five minutes longer. 10 A.M., pulse poorer and poorer, but somewhat slower; great pallor. 10 A.M., as the patient was being placed upon the table, apparently dead, I punctured the cul-de-sac, as I could not believe that the pulse could keep getting slower with a fatal hemorrhage. Fresh blood gushed from the puncture. Abdomen was rapidly opened, without stopping for anesthetic. Patient, unconscious, gave no sign of life. Abdomen full of bright red blood. The hemorrhage was stopped, the abdomen washed out with hot saline; while the abdomen was being closed intravenous saline was given. As soon as the hemorrhage was stopped and the hot saline started, the pulse returned, and the patient commenced to show signs of pain. A few whiffs of chloroform were then given. Half an hour later the pulse was 140 and it soon fell to 128. The temperature and pulse stayed high for three days and the patient had headache. The wound healed by first intention, and by the end of a week she was in excellent condition.

Now, to return to the *conditions found at the operation.* There were no adhesions and no mass was present. I reached in and pulled up the right tube and ovary. They were normal and were dropped back. I then reached the left tube and ovary, and was surprised, as they also were normal. Dropping the left tube and ovary I reached the uterus and pulled it up into the incision. It was enlarged, as if about six weeks pregnant. A ragged rent was found in the right cornu of the uterus, large enough to hold a horse-chestnut. Chorionic villi could be seen in this cavity. The tube itself looked perfectly normal, but was entirely separated from the uterus. An artery coming up at the side of the uterus was pumping a large stream, with great force. This artery was tied, and the opening in the uterus was closed, after the ragged edges had been cut out, by an incision which extended down to the uterine mucosa, including an oval two by one inch and nearly one inch deep. The fetus was found floating in the blood.

Observations.—This case demonstrates some of the difficulties in making the diagnosis in hemorrhage. It illustrates the advantages of the saline infusion. It proves the danger of rupture by examination.

With regard to the pulse rate, this case has taught me the danger of being misled by a pulse which becomes slower even while a hemorrhage is taking place. The slowing of the pulse might be accounted for by the suddenness and rapidity of the hemorrhage, which induced syncope on the one hand, and thus lowered the arterial tension; and, on the other hand, left so little blood in the veins, that the ventricles were a longer time in filling. This slowing has not occurred in less rapid hemorrhages which have come under my observation. For instance, in an extrauterine pregnancy operated in the same hospital a few months ago, the rupture was at the middle of the tube, and while severe and protracted, was not violent.

Case II.—March 20, 1903. Mrs. J., aged thirty-two years; one child, three years old. Menstruation normal and regular until last time, which was six weeks ago; no blood since. Two days ago, when twelve days past time to menstruate, she was taken in the night with sudden pain, which has continued with great severity.

Examination.—Breasts negative; cervix soft; uterus large with a mass behind. Dr. Levy, who sent the case into the hospital, had made the diagnosis of ruptured extrauterine pregnancy, and it was evident that the woman was bleeding. Her husband, however, refused to allow an operation to be done until twelve hours later, by which time he himself could see that she was dying. The pulse *gradually increased in rapidity all day,* until, when we operated, it was 200, and imperceptible at the wrist.

While writing these notes, we have had another experience. February 10, 1904, with hemorrhage in extrauterine pregnancy; a typical case, tubo-abdominal, in which primary rupture must have occurred during December at eight or ten weeks.

Case III.—Mrs. E., aged thirty-three years; three children, eight, five and three years old. Menstruated regularly; the last time October 10, 1903. In November was two weeks late, and flowed much less than usual, and has since had irregularly a dark, bloody discharge. The patient had very sharp pain a few days before Christmas, was tender and faint, and has since had several attacks of severe pain with faintness, and on December 29, fainted away. Has become very anemic. Temperature has been found 98 to 101° F., and pulse 90 to 120. No nausea or chill. Has had much vesical irritability, and believed herself pregnant. Examination February 9 revealed fluid in the breasts; color of vulva normal; cervix very

soft, with a large mass behind and at the right of the uterus. Temperature 99.4° F., pulse 100. The danger was explained, and an operation advised; but it took six hours of hard pain to make up the patient's mind. She came into the Hospital of the Good Shepherd at 3 P.M. February 10, and was operated at 4 P.M.

The patient was extremely anemic, blanched, her blood vessels seemed empty, she was greatly distended, and the operation revealed, in addition to large masses of clots of various ages, an abdomen filled with dark red blood, that must have escaped during the preceding twenty-four hours; enough in quantity to exsanguinate the patient, and undoubtedly enough to have killed her had the hemorrhage been rapid. Yet before the operation the pulse was only 120, and it did not go above 150, when she left the table it was much lower, and soon fell to 120; and her recovery was rapid.

It may happen that a patient who has had a frightful hemorrhage may have a slowing pulse or even a fairly slow pulse, depending upon the rapidity of the hemorrhage and its cessation or continuance. In a probable abdominal hemorrhage in a woman, a vaginal puncture may be advisable to settle the question.

With Regard to the Intravenous Saline.—The administration of an anesthetic and manipulation of a half hour abdominal operation, are a great strain on a patient who is in good condition, and we expect shock. But when the patient is on the verge of the grave from a rapid and severe hemorrhage, already in profound shock, gasping for oxygen, what shall we say of the prospect of giving an anesthetic and opening the abdomen?

We cannot wait for our patient to rally, for we have no right to expect the bleeding to stop, and we are obliged to proceed at once. When the anesthetic has been given ten minutes, and the arm of the operator is down to the elbow in the blood in which the intestines are floating and in which nothing can be seen; while the hand is picking out and bringing up the bleeding area from beneath the clots where almost nothing can be felt; with the patient still bleeding and having no blood to be lost, the case becomes desperate indeed and the shocked condition of the patient is terrible. She stops breathing, and the anesthetic is taken away; and the man at the pulse is wont to say, "It is of no use, pulse 150—180—gone."

However, a change occurs, for with everything in readiness, in the second that the operator has clamped around the bleeding area, the saline has been started and oxygen applied, and as the amount of saline administered is read off 200 c.c., 250 c. c., 400 c.c., the pulse begins to return and is called off 180 160 140, the respirations are gradually resumed; the change is remarkable, the operation is satisfactorily completed, and the patient leaves the table in excellent condition.

These three cases were saved by the intravenous infusion, and it would be great folly to operate for ruptured extrauterine pregnancy without being prepared to use the saline. In accident cases, with crushed limbs and injured nerve centers, the vasomotor system is paralyzed and the saline is disappointing; but in hemorrhage cases with the artery tied, the effect is magic. The flow, however, should not be started until the hemorrhage has been stopped, or the loss of blood will only be increased. And the danger of giving too much saline is great and grave, and should ever be kept before us. If the blood is too much diluted, the tendency to bleed is greatly augmented and the surfaces of adhesions otherwise harmless, may ooze profusely, prolonging the operation.

The proper amount of saline is small, for the blood pressure is soon restored. After enough has been given, fluid begins to pour out through the gastro-intestinal and respiratory mucous membranes as fast as it runs into the veins, and if continued the blood pressure rapidly falls, the lungs, liver, and other organs becoming edematous, and the patient is drowned. The old directions were to crowd the saline, giving four quarts or more if necessary, that is, if the blood pressure did not keep up, and many and many of these patients were said to die in spite of four quarts of saline.

Crile[1] has shown the good and bad effects of saline infusions. In his experiments on dogs, although some were saved when a large amount of blood had been withdrawn and a large amount of saline introduced, especially when oxygen and artificial respirations were used, yet, in the average case, a fatal dose was found to be very small, about 6 c.c. of solution to each pound weight of the animal; and the saline was found to be particularly dangerous when chloroform was used.

In these three cases of hemorrhage from extrauterine pregnancy, as soon as the pulse was full and the second sound of the heart commenced to be accentuated, the saline was stopped. Each of these patients weighed about 120 pounds and of course their veins were empty when the saline was started. They received 700 to 1,000 c.c., or about 5 to 8 c.c. to each pound of their weight. In addition, each received about one pint in the abdomen, and one quart in the rectum, for later and slower absorption.

With Regard to the Danger of Rupture by Examination.—I believe an examination in a case of extrauterine pregnancy is apt to clear up any doubt in diagnosis, as it is certainly quite liable to rupture an early case, and start up hemorrhage in one that has already ruptured.

When we look back on our cases, we see that the symptoms following the examination were striking. And when we consider the conditions found at operation, we cannot see how the most careful examination can be made without the greatest danger. When a tube the diameter of a lead pencil is bulged out to hold a lemon or an orange, it is certainly on the point of tearing. And when partial rupture has already occurred, and the mass in the tube has begun to extrude through the rent; when the hemorrhage from the torn vessels has been stopped by a tender clot being spread out over the bleeding area, only to be torn away and

[1] Problems Relating to Surgical Operations, Lippincott, 1901.

plastered up again the next day, as the mass has become larger and has been further extruded; when a rupture is so liable that the patient is often awakened from quiet sleep by the agony of another explosion, does it not seem strange that it is ever possible to make any examination without accident?

As there were no clots present in the case of interstitial pregnancy, the sudden violent pain that had occurred a week earlier must have been caused by a stretching and tearing, that had not yet amounted to rupture; but as the operation, which was performed one-half hour after examination, found the abdomen full of red blood, we must conclude that the pregnancy was ruptured by the examination.

The first case, used in illustration, had commenced to rupture two days before the examination; possibly the clots found at operation had temporarily stopped the hemorrhage. However this may be, she certainly had bled from the time of the examination until the operation, and it would seem impossible that any reasonable examination could have been made without breaking up such soft clots as were present.

The other case had ruptured two months earlier, and was continuing as a tubo-abdominal pregnancy. The diagnosis was plain, but the patient refused to go to the hospital. However, during the next few hours after a most careful examination, so much pain and soreness were experienced, that the patient herself soon became anxious for the ambulance.

Being always so dangerous, it is of the greatest importance to recognize extrauterine pregnancy, and when in doubt it would be better if necessary to have the examination produce a little hemorrhage and clear up the diagnosis, rather than have the condition continue to develop. But the danger of rupture by examination ought to be remembered, and a suspicious case ought to be carefully watched for a few hours after an examination; and in a probable case, it would be much safer if the examination could be made in a hospital operating room, where a vaginal puncture and exploration could instantly clear away any doubt in diagnosis, and any necessary operation could at once be performed with safety.

A NEW BRACE FOR THE SHOULDER JOINT.[1]

BY LEONARD W. ELY, M.D.,
OF NEW YORK;
ORTHOPEDIC SURGEON TO THE ROOSEVELT HOSPITAL DISPENSARY, ETC.

THE accompanying drawing illustrates an apparatus which I devised some time ago for a case of tuberculous shoulder-joint disease. It is very simple and can be made by any brace-maker. It permits motion and use of the fore-arm, and restricts motion of the shoulder in every direction except rotation—the least harmful of all motions of the joint. It was devised for a case that had lasted a number of years and had undergone operation several times, and, after the lapse of about one year, appears to have cured the disease.

The brace consists of a belt of canvas three or four inches wide which encircles the chest just

below the axillæ, and laces in front. A similar belt encircles the arm. These two belts are joined by two flat, arching metal rods, in front and behind, on whose inner ends are riveted metal plates to prevent twisting of the thorax girdle. Finally the thorax band is provided with a pair of suspenders to prevent sagging.

The latest use I have found for this brace was in a case of recurring dislocation, but the patient, a bartender, found that it restricted the motion of his arm too much, and soon gave it up.

451 West End Avenue.

THE EARLY DIAGNOSIS OF POTT'S DISEASE.[1,2]

BY FRANK P. VALE, M.D.,
OF WASHINGTON, D. C.

THE best way to avoid overlooking Pott's disease, is to keep constantly in mind the possibility of its existence. Within a few months two cases have come under my notice in which, even at an advanced stage, the affection had not been recognized, though both presented the typical angular deformity which could have been immediately identified. When the disease gives us such unmistakable evidence of its presence there can be no possible excuse for a tardy diagnosis; yet no less an authority than Sir Frederick Treves, in a recent article in *The Practitioner* (London, 1903, p. 1), relates that he opened the abdomen of a patient with persistent gastric symptoms, only to have his attention called a few days after the unsuccessful exploration, to a "hump" on the back, which the nurse had accidentally discovered. And in both of the cases I have referred to, the clinical history should have brought Pott's disease to one's mind.

[1] Read before the Medical Society of the District of Columbia, March 30 1904.

[2] Received for publication March 28, 1904.

The first case was that of a male, aged thirty-five years. His chief complaint, when he came to me, was the loss of the use of his arms. Ten months before he had been thrown from his horse in stopping a runaway. For two weeks following the accident he had sharp pains between the shoulders. They then disappeared for a short time, only to reappear with renewed vigor. The loss of power in his arms began about three months after the accident. He was then easily exhausted; often it was necessary for him to get off his horse and lie down on the side of the road, thus obtaining relief from his pain. Three or four months later he began to suffer with an oppression and pain in the chest, especially on exertion. At times he could not hold his head up and would have to support his chin with his hand. His voice became husky, and his respirations wheezy, and about this time a diplopia developed. An examination of his back revealed, at the cervicodorsal junction, a well-defined projecting knuckle. An interesting fact was the history of a localized tuberculosis of the testicle, four years before—also of traumatic origin—which had necessitated removal of the organ. Twice then he had developed a localized tuberculosis following an injury, but had never shown any other tuberculous manifestation.

The second case was that of a young man of twenty-three years. His first symptoms dated back four and one-half years. He would often stumble and soon noted some weakness of the legs. His gait was so unsteady he was frequently accused of drinking to excess, and such reports came to the ears of his parents. From that time there has been a progressively increasing paraplegia. It is almost inconceivable that during all this time his back has never been examined. The pains in his legs had been called rheumatic; when he came to me he complained especially of severe pain over the crest of the left ilium. The final heroic effort in his behalf had been made a short time before. He was circumcised with the hope of curing the loss of control over his bladder and rectum. His appearance proclaimed a grave malady. His paraplegia had reached the point where he could hardly walk; in fact, for a year he had only been able to walk with his bicycle beside him for support. I was almost certain of what I would find before I had him strip—and there was the characteristic deformity in the middorsal region. Two months in bed, and a plaster jacket worn since for four months have nearly restored his limbs to their normal condition.

But certainly with regard to these advanced cases we only need have our attention directed to the possibility of such errors, to sufficiently profit thereby. The recognition of the disease before this unfortunate deformity occurs gives us most concern, and is the matter of vital importance.

As an illustration of the disease at this earlier stage I present the case of a nine-year-old boy. When I first saw him it was stated he had been ill but ten days or two weeks. From his appearance one knew at once he was seriously sick. His sole complaint, however, was of pain in the stomach. He had always seemed perfectly well except for the apparently insignificant fact that for as much as two years he had at times complained of this pain. But as far as his mother's observations go his illness dates back not more than two weeks.

On examining the back there was no deformity or local tenderness. Partially supporting the weight of his body with my hands under his arms he volunteered the information that his stomach pain was relieved. In picking up an object from the floor his movements would hardly attract attention—there was no effort to support his weight with his hands on his knees, the rigidity of the back muscles simply prevented any arching of the spine. He hesitatingly jumped from a chair to the floor, but said it caused him no pain. Placing him face down on the examining table one could raise the thighs and pelvis and produce almost as extreme a flexion as normally, but when this was carried beyond a certain point he complained of exaggerated pain in the stomach. There was no psoas spasm. Lateral pressure on the ribs did not cause pain. He walked with his toes slightly turned in, and carried his shoulders thrown back and elevated. His abdomen was somewhat prominent.

Had a doubt existed as to the diagnosis it would have been removed by the radiographic appearances to be referred to later. The diagnosis has been confirmed by the further progress of the disease—though there is no deformity present, and I anticipate the disease will run its entire course without the appearance of any; a careful palpation in the middorsal region now reveals a very slight prominence of three spinous processes, and a little greater interval between them than is noted just above and below. The results obtained by the plaster jacket applied are also amply confirmatory, for without any other therapeutic measure being adopted the patient was immediately relieved of his pain, and has entirely regained a healthy appearance after an interval of two months. For two weeks, while his present removable jacket was being made, he wore one of plaster, which had been slit up the side and insecurely fastened, with the result that there was a return of the pain.

This history of abdominal pain is a characteristic one. We find it referred to even in the original paper of Pott in 1799. He says: "And soon the patient complains of frequent pains and twitchings in his thighs, and of an uneasy sensation at the pit of his stomach." About fifty years ago Benjamin Lee (*Angular Curvature of the Spine*, Philadelphia, 1867) especially emphasized epigastric pain as an important, early and characteristic symptom of spinal caries. "This pain," he writes, "is almost invariably the first symptom of the commencing caries, or of the inflammation of the periosteum or intervetebral cartilage which precedes the caries. In nine cases out of ten the disease is ushered in by attacks of gastralgia. The

length of time during which the patient suffers from it before the ulcerative process has destroyed enough of the bone to produce actual and unmistable deformity is variable, but it has been noticed not infrequently six months, and in some cases an entire year previous." In this boy there had been attacks of epigastric pain for two years, but it had received no attention until his appearance suggested there was something seriously wrong with him.

Pain at the site of the disease, however, is not significant or constant, but, on the contrary is referred to the area of distribution of the spinal nerves taking their origin in the affected region, producing these characteristic gastralgias when the disease is located in the middorsal vertebræ; the pain being referred to the rectum, bladder and lower limbs when the lumbar vertebræ are involved, and to the arms, chest and occiput when it is the cervical vertebræ. Pain in the back then, is a symptom frequently inquired for, but usually absent. But any peripheral pain, which does not yield to ordinary measures, should cause the spine to be carefully examined.

In some cases all pain is entirely absent, and the general impairment of health—which the physician is at a loss to explain—may be the only evidence of the slumbering inflammatory process. In rare instances, without either pain or marked impairment of the general health, the disease may progress to the stage of deformity without attracting attention. Even in the early literature of the disease we find mention made of this. Sir Benjamin Brodie (*Diseases of the Joints,* London, 1818) described "A case in which the patient had made no previous complaint, immediately after a slight exertion experienced a sudden pain, as if something had given way in the back, and at once lost the use of her lower limbs, and observed that the spinal process of one of the lumbar vertebra made an angular projection." Large abscesses formed, and she soon died.

Local tenderness on percussion, and sensitiveness to heat or cold, are signs to which diagnostic importance have been attributed since the earliest descriptions of the disease. James Earle, a contemporary of Pott, said (*Observations on the Cure of Curved Spine,* London) in 1799: "If suspicions are directed toward the back, the seat of the mischief may often be discovered by pressure with the fingers, or with the knuckles, gently on each vertebra, singly one after the other." Local sensitiveness to heat was first mentioned by Copeland in 1815 (*Treatment of the Diseased Spine*). He discovered it accidently, he writes, in applying a moistened sponge to the spine, and cites a case in which, by the aid of this symptom, he recognized the disease before the occurrence of deformity. But the rapid cure obtained by his application of "caustic issues" causes one serious doubt as to the accuracy of his diagnosis of spinal caries. Even in our twentieth century text-books, especially those from German authors (Hoffa, Mueller, David), we find these signs enumerated, though I express my own skepticism as to their value. A modern modification, to which they also refer, is that suggested by Rosenthal and Seligmüller—the sensitive spot being sought by the aid of the galvanic current, with the cathode in the epigastrium and anode applied along the spine.

Jones and Ridlon in a series of contributions to orthopedic surgery (*Provincial Medical Journal,* November, 1892) thus express themselves on this point: "There seems to be an almost universal belief among the profession, and this belief has been fostered by nearly all teachers and writers on general surgery, that the most early and constant —in fact the diagnostic—symptom of spondylitis is tenderness on pressure over the point of disease. There is no lack of knowledge as to the pathological anatomy; it is perfectly well known that the lesion is confined to the vertebral bodies and usually to their anterior portions. It is therefore quite impossible that there should be tenderness over the spine or transverse processes. Unless, then, there be disease of the processes or laminae, an exceedingly rare condition; or unless an abscess, which will not be readily detected by palpation, be present, tenderness on pressure will not be found in spondylitis. In a doubtful case its presence must count as an important symptom against true spondylitis."

In the early diagnosis of this disease the symptom of greatest value, the first to appear and the last to disappear, is muscular spasm. The same condition exists around chronically diseased joints of the extremities. This muscular rigidity is nature's method of limiting motion, relieving pain and insuring rest. Rest is nature's panacea; with the fluoroscope look through a chest at the lung acutely involved in a tuberculous process, and you see evidence of the same effort at repair through rest—the diaphragm on the affected side is almost fixed, its respiratory excursions practically nil.

This muscular spasm shows itself in different ways according to the region of the spine involved. In cervical caries it often produces "wry-neck." If suspicion is fortunately directed to the spine, one is confirmed therein by the relief obtained from extension applied to the head with the patient in bed. If one does not keep spinal caries in mind, unsuccessful tenotomies are sometimes performed. In young children, in the absence of wry-neck serving to attract attention to muscular rigidity if cervical disease is suspected, place the little patient across your knees and, to again quote Jones and Ridlon, "if the disease exists the child will not let the head dangle, no matter how prolonged the examination may be."

In the lumbar region the mild lordosis seen in early cases is in part the result of muscular contraction, *i.e.,* psoas contraction—throwing the spine forward and necessitating the shoulders being thrown back—though in part voluntary, the patient naturally favoring this position as it takes pressure off of the diseased vertebræ. This

lordosis produces a prominent abdomen, which may be one of the first things noticed. Contraction of the psoas muscle at times produces a slight limp, or a sliding gait. With the patient face down on the examining table and the pelvis fixed, this spasm of the psoas is shown by one's inability to raise the knee the normal two or three inches from the table. This contraction of the psoas, flexing the thigh and limiting its extension, often leads to a mistaken diagnosis of hip disease. It has been seen so great as to necessitate the child walking on "all fours." With the patient prone, any rigidity also of the spinal muscles, even of the upper dorsal region, can be readily appreciated, by estimating the flexibility of the spine in raising the feet and pelvis from the table. In health this can be carried until the thighs are nearly at right angles to the back. Probably the best way to demonstrate any abnormality in the regular contour of the back, or limitation of its flexibility, is to have the patient stoop, or bend the body forward as far as possible while in a sitting position. The usual test is to have the patient pick up some object from the floor; the body will bend from the knees and hips, while the spine is held rigidly erect. In fact the rigidity of the back muscles is shown in every movement made.

There is one other effect, at least in part due to spasm of the back muscles, and that is diminution in the patient's height, which may be considerable even in the absence of deformity.

Paralysis of both legs, less frequently the upper extremities, may be the first symptom noted, at times antedating the appearance of the deformity several months. This "palsy" of the lower limbs was the one symptom which first led Pott to make a study of the disease. He says: "When the disease attacks a child who is old enough to have walked properly, its awkward and imperfect manner of using its legs is the circumstance which first excites attention, and the incapacity of using them at all, which very soon follows, fixes the attention and alarms the friends. . . . He at first complains of being very tired, is languid, restless and unable to move much, or at all briskly, for no great length of time. After this he may be observed to trip and stumble, although there is no impediment in his way; and whenever he attempts to move he finds that his legs involuntarily cross each other, by which he is frequently thrown down, and that without stumbling; upon endeavoring to stand still and erect, without support, even for a few minutes, his knees give way, and bend forward. When the disease is a little further advanced, it will be found he cannot, without much difficulty and deliberation, direct either of his feet precisely to the exact spot, and very soon after this both thighs and legs lose a good deal of their natural sensibility, and become perfectly useless for all purposes of locomotion."

If this disease is very liable to be overlooked in adults, how much more is this likely in children who cannot explain their ill feelings. Pott's statement that: "When the disease attacks an infant of only a year or two old, or under, the true cause is seldom discovered until some time after the effect has taken place" is about as true to-day as it was then. Paralysis is shown in an infant only by the loose, flaccid manner in which the limbs lie, though the way it climbs to a sitting posture by seizing the edge of the crib might attract attention. The child lies quietly, if undisturbed, but cries at the slightest touch or the approach of any one.

In the examination of infants, Sayre was in the habit of taking the child across his knees and in separating them note the effect of the slight traction thus made—pain and difficult breathing often disappearing in a significant manner. It was Sayre who pointed out that in the dorsal part of the spine the sides of the vertebræ are primarily and most extensively involved. Lateral pressure on the ribs so as to force their heads against the facets produced pain, which he regarded as a valuable diagnostic point.

Waterman and Jaeger (*New York Medical Record,* November 9, 1901) after a study of a thousand cases on the record books of the New York Hospital for the Ruptured and Crippled, state that the first symptom noticed in infants and children under five years of age, was an unnatural attitude. Gastralgia, night cries and progressive weakness were the next most common first symptoms, while grunting respiration, inability to walk, and abdominal protrusion were present in but a very small number.

In disease of the upper dorsal vertebræ the chin is raised "suggesting the position of a seal's head when out of water" (Bradford and Lovett). In caries of the middorsal spine the shoulders are elevated and thrown back, thus relieving the bodies of the diseased vertebræ from pressure and aiding in the fixation of the spine. The patient walks with toes slightly turned in so as to prevent the heels from striking, and with more weight on the toes than on the heels, the better to prevent jarring of the back. In cervical caries a favorite attitude for the child is with its chin supported on its hands and elbows on a table or on its knees.

In this early case of Pott's disease I have brought before you the X-rays were a factor in confirming the diagnosis. The radiograph shows the space between the eighth and ninth dorsal vertebræ nearly obliterated. Superimposed on the cardiac shadow there is a fusiform shadow jutting out from the spinal column from the seventh to the tenth vertebræ, quite marked on the left side but less distinct on the right. It outlines the inflammatory exudations at the site of the disease.

It is surprising how little has been written on this subject of the X-ray appearances in early Pott's disease. Every one is agreed upon the difficulty attending the recognition of the disease before the appearance of the deformity, yet the references in medical literature to the value of the X-rays in this connection can be counted on

the fingers of one hand. In an article on the cure of spinal caries without subsequent deformity, by Royal Whitman, in the *Transactions of the American Orthopedic Association,* 1901, p. 359, is a cut showing the X-ray appearances in a case of early lumbar caries. Redard and Loran in 1898 at the Twelfth French Surgical Congress, p. 228, spoke most enthusiastically on this subject. In many of their observations an X-ray examination enabled them to establish the diagnosis of Pott's disease in its earliest stage, when the subjective and objective symptoms were not enough by themselves to justify it. Their plates showed the number of vertebræ involved, extent of lesions, loss of substance, existence of sequestrae and tubercular cavities.

Kirmisson, another French orthopedic surgeon, writes the only other paper on the subject of which I have any knowledge (*Revue d'Orthopédie,* 1901, p. 405). The X-ray appearances in this boy correspond exactly with those described by him. He writes: "It is especially in the dorsal region that radiography furnishes the most precious information. In the lumbar region, in docile children, deep palpation of the abdomen. enables one to recognize, at times, without great difficulty, existence of caseous masses in front of the vertebral column, at times even small abscesses still distant from the anterior abdominal wall. In the dorsal region it is not the same, and neither palpation nor careful percussion enables one to affirm the existence of an abscess. There is here, unfortunately, an anatomical fact which is inconvenient in the appreciation of the results furnished by the X-ray negative—the presence of the cardiac shadow. However, one readily learns to recognize the characteristic outline of this latter; and further, even when the cardiac and Pottic shadows are superimposed, one on the other, the shadow due to the vertebral lesion generally being the more pronounced. One is able to recognize the fusion of several vertebral bodies by the disappearance of the clear intervals corresponding to the intervertebral disks. and to see that the vertebral column is often surrounded by a more or less round or fusiform exudation which juts out from each side of the vertebral bodies. This fact is *en rapport* with that remarked by all observers occupied with the pathological anatomy of Pott's disease—that clinically a good number of patients have no abscess; while on the contrary, when one has occasion to make anatomicopathological studies one is struck to see that in reality the majority of cases of Pott's disease are accompanied by suppuration."

I may add to the remarks of Kirmisson the well-known fact that in early cervical caries it is often extremely difficult to differentiate the muscular spasm associated with this condition from that of true muscular wry-neck, and, as a last word, enter a plea for the more frequent use of the X-rays, in connection with other diagnostic methods, in one's efforts to recognize spinal caries at an early date.

MEDICAL PROGRESS.

OBSTETRICS AND GYNECOLOGY.

The Apostoli Treatment.—The value of this method of treating uterine fibroids by electricity was hotly contested in medical literature some years ago and a sufficient length of time has now elapsed to permit of dispassionate conclusions. G. B. MASSEY (*Jour. Am. Med. Ass'n,* May 21, 1904) reports the results he has obtained with the method during the last sixteen years in a total of 110 cases. Excluding nine cases where the results are unknown, the remaining patients which could be reached by various methods of inquiry, were found to exhibit 75 actual or practical cures, and 26 failures. In other words, three-quarters of the cases were successes and one-quarter failures. The latter term was made to include those cases where the patient was left in a condition the same as before treatment, and in a position to accept operative removal if necessary or desirable. In 18 instances the tumor had totally disappeared, although not all these cases were verified by the author. He concludes that we expect a cure in three-quarters of all the cases subjected to the Apostoli treatment, as attested by inquiries made from three to sixteen years after cessation of treatment. The cases that respond poorly, or not at all, are not harmed by the treatment when properly applied, and heroic measures may then be adopted with the certainty that milder ones are of no avail. Hemorrhagic and interstitial fibroids are best adapted to the method, while subperitoneal or degenerative fibroids, and those complicated with pyosalpinx are least adapted to be relieved by it. Among the author's patients there were seven deaths during the sixteen years they were under observation, and only one of these was due to the progress of the growth itself. Of the others, four died while being operated, one of an intercurrent disease and the other of septicemia.

Urea in Puerperal Eclampsia.—Since the test for albumin in pregnancy has at times proved unreliable, an estimation of the quantity of urea excreted has been generally accepted as a sure indication of threatened eclampsia. But even this has come to be regarded by some as an overrated danger signal and the favorable termination of cases where the excretion of urea was far below the normal has led to a closer study of the subject by F. S. CLARK (*Cleveland Med. Jour.,* April, 1904). In 38 cases, with a total of 140 examinations, the highest percentage of urea excreted was 2.5 per cent. and the lowest 0.2 per cent., the average being 0.99 per cent., which is low as compared with the supposed normal amount. The average in weight was 13.57 grams. With three exceptions all the cases were free from suspicious symptoms, and in only one of these did eclampsia actually come on. It seems, therefore, that a diminution in the quantity of urea excreted during pregnancy does not signify that eclampsia is threatening. For this reason, if other conditions are normal, a systematic examination for urea is of no value and cannot always be depended upon, even in cases where other conditions are abnormal. It is true that such a small number of cases would give very inaccurate conclusions if it was attempted to establish the positive value of examinations for urea, but it does not require a large number of cases to establish the negative value of this factor. The author believes that it would not be right to put patients on a strict anti-eclamptic diet, when there is no other symptom than a decrease in the quantity of urea excreted. He still thinks that the presence of albumin is the best guide

for estimating the chances of an eclamptic attack coming on, and as the quantity may be very small, he suggests making two tests of each specimen. If it is then found only in traces, a microscopical examination should be made. The tests for urea only are of value when other symptoms of intoxication are present.

Treatment of Retroversion During Pregnancy.—The chief reason why this condition requires immediate and careful treatment is that unless the displacement is corrected it may result in cystitis; ascending pyelitis and death. It is commonly said that retroversion of the gravid uterus often results in abortion. This the author, G. Ernest Herman (*Brit. Med. Jour.*, April 16, 1904) disbelieves. In his opinion when the uterus has become large enough to be incarcerated under the sacral promontory, the period of abortion is passed and the danger to the patient lies not in the possible loss of her child, but in infecting herself secondarily through retained urine. Many of the retroversions which have gone on to miscarriage, have done so through rough handling in the attempt of practitioners to replace them. Busch, out of 74 cases found that in 69 the uterus spontaneously righted itself. Of these only four aborted or one in seventeen. Charles has analyzed 138 cases. In eight of these abortion was induced. In 88 the displacement was forcibly reduced, either manually or instrumentally, and in 11 of the cases abortion took place. Charles reports abortion in 37 of his 138 cases, including those which were induced. Of the 39 who spontaneously aborted, no less than 20 died. In St. Bartholomew's Hospital from 1881 to 1892, inclusive, 42 cases of pregnancy complicated by retroversion were treated. In 41 the uterus was incarcerated and was causing retention. In 25 the bladder was emptied and replaced. In ten cases the catheter was frequently used and the uterus spontaneously righted itself. The clinical side of this condition shows that the whole danger of retroversion of the gravid uterus in the fourth month comes from the tendency of the condition to cause retention of urine. The organ itself is probably not in the least injured. The one solitary treatment for the condition is the free use of the catheter. This, if used in time, is sufficient to relieve all symptoms. Keep the patient recumbent and the bladder empty, and in 90 per cent. of the cases the organ will right itself.

Primary Sarcoma of Vagina in the Adult.—Primary sarcoma of this organ is a very rare condition; this being the thirty-ninth case recorded. Henry Jellett (*Medical Press*, April 20, 1904) reports the case of a woman, fifty-five years of age. He believes it to be the only case on record as having occurred in Ireland. She had nine children, the last pregnancy being eleven years ago. Menopause five years before. Two years ago she noticed the occurrence of a profuse white discharge which persisted a half year and then became purulent. She lost weight and presented the usual evidences of malignant cachexia. On physical examination anteriorly a curious flap existed beneath the orifice of the urethra. The whole of the vaginal wall was profoundly involved, but the parts were remarkably insensitive. One of the small bosses at the junction of the posterior and lateral wall was removed for microscopical examination. The removal of the growth was undertaken because it was eventually shown to consist of a round-cell sarcoma. The injection at a half-dozen points of a few minims of a 1 to 5,000 solution of adrenalin rendered the operation comparatively bloodless. The urethra was then dissected out and the terminal portion removed. The whole vagina was then completely surrounded by a circular incision and the growth was removed one-third way up the vagina. The vaginal wall was again circularly incised well above the growth and the upper and lower edges were approximated very much as in a Whitehead operation for hemorrhoids. The recovery of this patient was uneventful. The tumor proved to be an example of infiltrating sarcoma, the rarer of the two varieties met with in the vagina, the more frequent being the spindle celled. An admirable photograph of the condition is appended.

Rupture of the Uterus.—The following valuable conclusions are presented as the result of his own experience and the careful study of 50 cases reported in the literature by A. N. Dorland (*Medicine*, June, 1904). He divides the cases into fatal untreated, expectant without operation, and those treated by operation. He believes that incomplete lacerations of the uterine wall, if the hemorrhage be moderate and the diagnosis accurate, may be well treated by careful vaginal and intrauterine tamponade. Complete lacerations with invasion of the peritoneal cavity, should, under unfavorable circumstances, such as uncleanliness of locality and lack of surgical appliances, be temporarily treated by intrauterine tamponade and the administration of astringents and stimulants; the patient should then, if possible, be conveyed to some hospital and the abdominal cavity opened. Under favorable circumstances the cavity should be opened as speedily as possible and the rupture in the uterine wall sutured in suitable cases, or a Porro operation or a total extirpation be performed, according to the nature of the case. The general mortality was 24 per cent.; that with expectant treatment, 25 per cent.; and the operative treatment presented a mortality of only 16 per cent.

Rupture of the Fetal Membranes Without Terminating Pregnancy.—This accident assumes two forms the amnion alone may be ruptured and the fetus remain within its folds, or both chorion and amnion be torn and retracted from about the fetus, which then lies free in the uterine cavity. This subject has been studied by H. Meyer-Ruegg (*Zeitschr. f. Geb. u. Gyn.* Vol. 51, No. 3) who reports two cases of this obstetrical complication. In the twelve instances of rupture of the amnion alone thus far reported, the pregnancy continued to term, but only one of the children escaped without injury, the remainder being subjected to amniotic adhesions which resulted in amputations. In fifteen cases where both membranes were ruptured, pregnancy also continued to the sixth to eighth month. In eleven cases the fetus assumed the breech position. The opening in the membranes was always small and no inflection resulted. The expansion of the chorion frondosum was less in extent than that of the serrotina, and a marginal implantation of the placenta resulted. The prognosis for the child in these cases is always bad. The only reliable symptom of the condition is a hydrea, but which, during the early months, must be distinguished from the discharge due to an endometritis. No definite recommendations are made as to treatment.

Version in Primiparae with Narrow Pelves.—In special cases where a primapara presents a flattened pelvis, P. Broese (*Zeitschr. f. Geb. u. Gyn.*, Vol. 51, No. 3) recommends deep perineal incision extending into the cervix, followed by extraction. If version is difficult, he employs the following manual procedure. The hand is introduced between the head and the uterine wall with the volar surface turned toward the child. Strong traction is then made on the foot with

the other hand, and the head readily slides over the hand into the cavity of the uterus without boring into the cervix. He reports ten cases treated in this manner, with eight living children, the other two dying of cranial injuries shortly after birth. Other means had failed and perforation would have been indicated. The incisions are carried in the direction of the ischiorectal fossa, on either side of the rectum toward the tuber ischii. They must be carefully repaired after extraction and in every case presented, healed by primary union, and did not interfere except in one instance with subsequent labors. The operation is distinctly limited to cases where the diagonal is at least 10 cm., otherwise abdominal section or perforation in advanced cases, is indicated.

Effect of Escharotics on the Endometrium.—A very satisfactory insight into the question as to the actual value of the application of escharotics to the interior of the uterus is afforded by the investigations of A. RIELANDER (*Zeitschr. f. Geb. u. Gyn.*, Vol. 51, No. 3). In four cases of intended hysterectomy for atheroma of the vessels producing severe hemorrhages or for retroflexion with fixation, he was able to apply the various agents some twenty-four hours previous to the radical operation and then to study the effect on the extirpated organ. He found that alcoholic solutions of a remedy are to be preferred as they are distributed more readily over the surface and penetrate to a greater degree than those of an aqueous character. Playfair's sound is sufficient for all purposes. The uterine mucosa is easily penetrated by escharotics, but the more compact muscular layers offer a marked resistance. The aqueous solutions penetrate very slowly, the alcoholic more rapidly. The application of a 30 per cent. alcoholic solution of formalin is followed by a throwing off of the scab within twenty-four hours and then the regeneration of the mucous membrane begins at once. Although the attempt was made it was impossible to affect, in any way, the mucosa of the tubes by the applications carried in on the Playfair sound, and the author doubts whether the reported cases of the latter procedure can be confirmed.

THERAPEUTICS.

Marmorek's Antituberculous Serum.—The claims of the originator of this preparation have been conservative. He states that if investigators find, as he believes he has been so fortunate as to do, that the serum does no harm in any case and in a few chosen cases enables one to ameliorate the symptoms and diminish the extent of the ravages of the disease, any physician is justified in giving the serum a trial. ARTHUR LATHAM (*Lancet*, April 9, 1904) states that he was so fortunate as to have the advantage of a visit from Dr. Marmorek on three occasions at the Brompton Hospital for Consumption, and that through his courtesy he was enabled to give the serum a rather wide trial. The technic of giving the injections defers more or less to the fancy of the patient, except that in surgical cases, it is probably advantageous to give the injection somewhere in the neighborhood of the lesion. A very excellent plan to adopt is the covering of the selected area with cyanide gauze and contenting oneself for each subsequent injection with a swabbing of the skin with some antiseptic before using the needle, too extensive preparation tending to produce a very irritating dermatitis. The author has given over 415 injections in this way without any accidents. The puncture should always be closed by collodion. The time of the injection is preferably between nine and eleven o'clock in the morning. The effects of the serum, as immediately observed, are probably attributable to the "horse" in the serum and not to the antitoxin. The idiosyncrasies of certain individuals are as marked in reaction to the preparation as they are in any other serum. The rashes differ in no way from the ordinary serum rashes. They typically occur after three or four injections. The antitoxic effects of the serum are not yet definitely proven. It is, however, already clear that the serum has its limitations. These are found prominently among the older cases, although even in this class the patients have invariably expressed themselves as feeling more comfortable from the treatment. The author concludes that the serum does produce a distinctly antitoxic effect. He believes it to be specifically curative in some of the recent and less severe forms of infection. It must not be forgotten, however, that this treatment must be carried over a long series of months in order to obtain any definite results.

A New Salicylic Acid Preparation.—The desire to put on the market a preparation of salicylic acid which is readily absorbed by the skin, has led to the manufacture of salit, an oily, unsoluble fluid which is readily split up in the body into salicylic acid and borneol. P. MÜLLER (*Münch. med. Woch.*, April 12, 1904) rubs a teaspoonful of a 50 per cent. solution in olive oil twice daily over the affected spot. Muscular rheumatism, acute neuralgia, mild acute polyarthritis, acute pleurisy and acute tendovaginitis were influenced most favorably; some improvement followed in severe polyarthritis, chronic rheumatism and neuralgia and tuberculous pleurisy, while gout and erysipelas were not affected. After-effects were not noticed, but in patients with delicate skin an itching eczema sometimes appears.

Treatment of Hay Fever.—E. FINK (*Therap. Monatshefte*, April, 1904) criticizes strongly the antitoxin treatment of hay fever and looks upon this disease as a purely local process in the antrum of Highmore, caused generally by pollen. A rhinoscopic examination during an attack will invariably disclose an excessive discharge in the middle meatus and a trocar introduced into the antrum will draw off fluid. The patients are generally neurasthenics and very prone to react to slight stimulation. Secondary symptoms such as conjunctivitis and asthma are merely reflex disturbances. The most satisfactory treatment is the application of aristol directly to the mucous membrane of the antrum by means of a thin canula. Six or seven applications are usually sufficient, but it is generally advisable to repeat the treatment every season.

Treatment of Acute Articular Rheumatism.—With reference to treatment, articular rheumatism may be divided into three classes, viz., (1) where the salicylates have a prompt and permanent effect, (2) where they merely alleviate the pain and inflammation without influencing the course of the disease, and lastly where no improvement is achieved. Of the many ways of giving sodium salicylate, the one by mouth is still preferred, though gastric irritation is apt to follow and the amount of drug which actually enters the circulation is certainly small. One can hardly speak of a local action in topical applications of oil of wintergreen or the more recent mesotan, since these drugs are absorbed by the lymphatics before reaching the joint structures. Subcutaneous injections are generally too painful, but a great future is promised by F. MENDEL (*Therap. Monatshefte*, April, 1904) for the intravenous application. He uses a solution containing 8 gm. sodium salicylate, 2 gm. caffeine-sodium salicylate to 50 gm. of water and injects in amounts of 2 gm. directly into the veins at the elbow. The result was most remarkable, since in all rheumatic affection the pain and swelling disappeared almost at once, even when large internal doses of aspirin had been

without effect. After-effects were slight; occasionally trifling pain is complained of at the site of injection, or the patients experience a moderate chill. Disagreeable symptoms seen after internal use, such as vertigo, profuse perspiration, nausea or renal irritation were never noticed.

A New Mercurial Salt in Syphilis.—Hydrargyrum anilinicum.—While treating a tuberculosis patient for syphilis with sublimate compresses, FEDCHENKO (*Roussky Vrach*, No. 12, 1904) happened to obtain favorable results from an accidental admixture of anilin to the sublimate, which thus formed a new mercurial salt. It appears as a very light, downy white powder, tasteless and odorless, showing under the microscope small thin crystalline rods. Its chemical formula is $Hg(C_6H_4NH_2)_2$, thus containing 52.1 per cent. of pure mercury, or 56.3 per cent. of the oxide. It is but little soluble in water. The author used it first in an experimental way for four years, and then during the next eight years more or less extensively. It is mostly employed by him hypodermatically as per following formula:

℞ Hydrargyri anilinici 4.0
Oleo vasel. pur. steril..... 30.0
Cocaini nitrici 0.25

M. f. l. a. suspensio. Da invitri albo cum epistomio vitreo et cum collo lato. Formulam signe in eticeto.

Even when injected often and in large quantities there were observed no deleterious effects, such as abscesses or any other inflammatory condition; whatever little swelling did accompany the injection, was not of that hard and painful consistence that is met with in hypodermic injections of insoluble mercurial salts; besides the swelling disappears in a comparatively short time. Gingivitis was observed only in cases where large injections were made at the beginning without first habituating the patient's system to the drug. As regards the results of treatment, the author states that under it he caused the disappearance of syphilitic roseola during the first week of the injections, papules disappeared generally in two weeks, while the more obstinate lichen syphil. and psoriasis palm. as well as the ulcerative forms tended to yield after the fourth or fifth séance. The author advises that in cases where the patient can be placed under the full control of the physician the aniline salt of mercury is much more preferable to other salts in the treatment of syphilis. Not only is it rapidly absorbed, but it is just as rapidly excreted; thus the urine showed a mercury reaction after the second or third injection. The dose of the drug is for an average man one-fifth grain per day, beginning with one-seventh. The author also recommends the drug in a salve as well as internally in pills, and gr. ¼ in a pill; 4 to 8 or 10 to be taken every day. Patients bear the interval administration well and without any gastric disturbance. In general the drug should be employed more extensively, so that its effects might be established beyond any supposition or doubt.

Action of Alkalies on Gout.—The highly interesting article of F. BAHRMANN (*Arch. internat. de Pharmacodyn.*, Vol. 12, fasc. 5 and 6) deals with experimental gout, such as can be readily produced in chickens by feeding them exclusively on meat. The animals remain alive and sometimes even increase in weight, and after several months, characteristic deposits of urates will be found in the joints, pleura, etc. To test the action of various salts, lithium carbonate, soda, common salt and magnesium carbonates, respectively, were mixed with the food, since lithium is used freely in gout and its efficacy is contested by many. It is unfortunate that the animal invariably died shortly after this salt was given, since it apparently has toxic properties for birds. In the animal treated with soda, a deposit of urates did not occur; the action of magnesium was less marked while sodium chloride seemed to have no effect. Quantitative analysis of the feces proved that the excretion of urates is diminished. Not because they are retained in the system, but because they are manufactured to a less degree by the body.

Action of Alkaloids of Ipecac.—P. ZEPF (*Arch. internat. de Pharmacodyn.*, Vol. 12, fasc. 5 and 6) has proven experimentally that cephaeline and emetine have the same action upon man, but the emetic action of the former is considerably stronger. Locally applied to the upper or lower portion of the alimentary tract, both alkaloids are very irritating. An improvement in appetites was never seen; on the other hand, anorexia, aggravation of already existing stomach troubles and headache were quite frequent. Nausea regularly precedes emesis and there are no advantages over the powdered root. An action upon the upper respiratory tract is undoubted and is similar to that of quillaya or senega, but the effect is so slight after oral administration that there is hardly any sense in giving ipecac in tuberculosis. Much more can be expected from gargling or inhalation. A depression of the central nervous system by both alkaloids also took place, while the action upon the heart was not studied.

A New Curative Serum for Dysentery.—Since the discovery of the specific cause of epidemic dysentery by Shiga, various attempts have been made to secure artificial immunity against this disease. L. ROSENTHAL (*Deutsche med. Woch.*, May 5, 1904) after successful experiments in immunizing rabbits and guinea-pigs, used the serum on human subjects. The serum was obtained from horses and it was found that if 0.5 c.cm. were injected into a guinea-pig the day after the infection the animal would be saved, whereas the control animal died within twenty-four hours. The serum is also antitoxic. From 20 to 40 c.cm. were administered in each case and the only after-effects noted were a slight pain at the site of injection, erythema or urticaria. Altogether 157 patients were treated, among whom there occurred eight deaths, about 4½ per cent. The usual mortality rate in the hospitals at Moscow varied from 12 to 17 per cent. In conclusion, the author claims that the serum has a favorable effect on all the subjective and objective symptoms. The pain and tenesmus becomes less at the end of twenty-four hours, blood disappears from the stools, the duration of the disease is lessened, and the chronic form seldom supervenes, and the death rate is reduced by over one-half. If the serum is administered within the first three days after the disease has begun, convalescence is rapidly established within one or two days.

Phototherapy with Fluorescent Solutions.—Very excellent results have been seen by D. JESIONEK (*Münch. med Woch.*, May 10, 1904) from the application of fluorescent substances, such as eosin, to various skin diseases. The parts are repeatedly brushed with a 0.01 to 5 per cent. solution and then exposed to sunlight, or on cloudy days to the action of an electric arc light. The best results are obtained if the light is focused, by means of lenses, directly upon the diseased area, but to avoid excessive heat, a heat-filter containing copper sulphate and picric acid must be interposed. Artificial light is much inferior to sunlight and several cloudy days always prolong the cure. Dilute solutions are generally preferable, since stronger ones will lead to excessive crusting, especially in cancerous ulcers, which no longer permit the rays of light to penetrate. The solution may also be injected directly into the diseased tissue. At night the parts are covered with a moist dressing.

Pharmacology of Sulphur.—When sulphur is brought into intimate contact with fresh intestinal mucous membrane, sulphureted hydrogen will be formed in a short time. Boiling does not destroy this action, which is entirely independent of bacterial life. The stomach does not possess this property even when washed free of acid. A. HEFFTER (*Arch. f. exp. Path. u. Pharmak.*, Vol. 51, Nos. 2 and 3) also found sulphureted hydrogen in the expired air when he injected sulphur into the circulation of animals. This is caused by easily oxidizable albumins in the blood-cells and the organs. It is thus easily to understand why sulphur taken by way of the stomach will increase the amount of sulphuric acid in the urine.

Alkaloids of Corydalis.—Of the eight alkaloids isolated from corydalis cava, formerly much prized in medicine, corytuberin differs pharmacologically from the rest, in that it does not cause a morphium-like narcosis and cardiac depression in frogs. The remainder, F. PETERS (*Arch. f. exp. Path. u. Pharmak.*, Vol. 51, Nos. 2 and 3) divides into three groups, viz., the corydalin group with paralysis of the cord, the corycavamin group with irritation of the motor centers, the bulbocapnin group with increased reflex irritability. The first group may be allied to the morphine group, the third to the codeine group of poppy alkaloids. Therapeutically, only the bulbocapnin comes into consideration, since it may be indicated in motor irritation.

Treatment of Psoriasis.—An ointment, said to be far superior to other applications in psoriasis, is recommended by D. DREUW (*Münch, med. Woch.*, May 17, 1903). It consists of salicylic acid, ten grams, chrysarobin and olenin rusci each twenty grams, green soap and vaseline each twenty-five grams. The alkalinity of the green soap neutralizes the irritating properties of the salicylic acid and chrysarobin, so that inflammation of the skin does not occur.

A New Hemostatic Obtained from the Spleen.—Stagnin is the name of a preparation recently introduced, which does not depend on its mode of action on the contractile power exerted on the blood vessels, as with the suprarenal extracts, but probably has the ability to influence the coagulation of the blood. The action is entirely a chemical one and local application is ineffective. It is particularly applicable to capillary hemorrhages and the author has used it successfully in a number of cases of metrorrhagia and menorrhagia. He thinks, however, that it would also be of service in other diseases accompanied by capillary hemorrhages, in the stomach, intestines or lungs. It is not recommended to supercede surgical treatment, but may be used in those cases where radical measures are not immediately indicated. The drug is an extract from the spleen of horses, obtained by antiseptic autolysis. In animal experiments there was found a reduction in blood pressure and an increase tendency of the blood to coagulate. The best way to give the remedy is by intra-muscular injections in the gluteal region. No unfavorable after-effects were reported in 59 cases of uterine hemorrhage treated with this drug. This communication was made by T. LANDAU and HIRSCH (*Berl. klin. Woch.*, May 30, 1904.

The Excretion of Strontium.—An experimental study of the paths of excretion of strontium has been made by L. B. MENDEL and H. C. THACHER (*Am. Jour. Physiol.*, April 1, 1904) with the following results: Strontium salts are eliminated to a relatively small extent only by the kidneys even after direct introduction into the circulation. The excretion in the urine begins soon, and ceases usually within twenty-four hours. The larger portion eliminated is found in the feces, whether the introduction be per os, subcutaneously, intravenously or intraperitoneally. The place of excretion is apparently restricted to the region of the alimentary tract beyond the stomach. A functional relation to certain phenomena of intestinal peristalsis is suggested. The rate of elimination is slow, and is apparently influenced by the calcium content of the food. Strontium is found deposited in the body chiefly in the bones; traces may be met with in the liver and muscles.

The Action of Various Poisons upon the Pulmonary Circulation.—The greater and the lesser circulations possess a different degre of susceptibility to the action of various drugs, as shown by the experiments of G. MELLIN (*Skand. Archiv. f. Physiol.*, Jan. 20, 1904). Thus, ergot acts upon the pulmonary much more powerfully in raising blood-pressure than upon the systemic circulation. The author questions the desirability of administering ergot in pulmonary hemorrhages, on account of this greater effect in raising the blood-pressure. The tincture and the infusion of digitalis and frequently digitalin, as well as the tincture of strophanthus and strophantin, which, as is well known, act powerfully on the greater circulation, produce little or no effect in the lesser circulation. Occasionally digitalin increases markedly the pressure in the lesser circulation. Amyl nitrite and nitroglycerin have no effect upon the latter. Even in minute doses adrenalin produces a powerful effect upon the systemic circulation, but produces a hardly perceptible variation in the pressure of blood in the pulmonary vessels.

Sodium Sulphite a Dangerous Food Preservative.—A series of experiments to determine the effects of the habitual use of sodium sulphite in the food, were performed in cats by C. HARRINGTON (*Jour. of Infect. Diseases*, March 19, 1904) with results which are valuable from the standpoint of public hygiene, considering the large amount of this substance used as a food preservative. Six cats were under observation, one being a contral and receiving the same weight of untreated meat. They were fed upon freshly-hashed beef, to which was added 20 per cent. of pure crystallized sodium sulphite. From the start, all six of the animals gained in weight, but about the ninth week, all except the control began to lose. At no time did any of the animals show any outward evidence of poisoning up to five months, when all were killed. On section the macroscopic appearances were negative in all respects, but microscopic examination showed a parenchymatous degeneration of the kidneys. Each showed marked fatty degeneration of the renal epithelium; and in one case there was an acute interstitial nephritis in addition to and probably dependent upon parenchymatous changes. The control cat showed no pathological changes whatever. The conclusion is drawn that at least for animals, and probably for the human subject, sodium sulphite is a dangerous admixture to food.

Radiographic Appearances in Pleurisy.—Dry pleurisy, it is easy to understand, must continue to depend for its recognition upon other than radioscopic evidence. J. F. HALLSDALLY (*Lancet*, Feb. 27, 1904) states that in pleurisy with effusion appearances vary according to the amount of fluid contained in the pleural cavity, and naturally upon the position of the patient. The greatest difficulty in the discrimination of fluid in the chest is met with in children. Here, therefore, radioscopy is of the very greatest service in giving aid to clinical signs. The chief points to note in conducting such an examination are: (1) The height of the fluid on the affected side; (2) the contour of the upper margin of

the fluid; (3) whether or not the outlines of the ribs can be distinguished; (4) the position of the heart, and (5) the movement of the diaphragm if this be visible. The conclusions that the author has reached by means of radioscopy are as follows: (*a*) The level of the fluid changes with the position of the patient unless the quantity of the fluid be great or it be encysted by adhesions; (*b*) that a purulent effusion yields the shadow of greater density than a serofibrinous effusion; (*c*) that the shadow is homogeneous, and in the case of serous effusion gradually increases in density from above downward; (*d*) that, however far the heart be displaced to the right, in most cases little alteration takes place in the position of the apex relatively to the base; (*e*) that other conditions being equal, the heart is displaced more when the effusion is left sided, and (*f*) that a somewhat triangular shadow, not normally visible, above and continuous with the shadow of the heart and pericardium is cast by the mediastinum which is displaced by the lateral pressure toward the healthy side of the thorax.

HISTOLOGY, PATHOLOGY AND BACTERIOLOGY.

The Glycogen Reaction in Blood.—The diagnostic import of this sign cannot be understood until the nature of the reaction itself is known. G. LOVELL GULLAND (*Brit. Med. Jour.*, April 16, 1904) states that Ehrlich described it in pus in 1883. Owing to the prominence of other blood reactions, however, it was for the moment lost sight of. But owing in part to the activities of Dunham, Locke and Cabot in America, interest in it has been revived. The method is simple. The solution which serves for fixing, staining and mounting is composed of iodine, one gram; iodine of potash, three grams; water, 100 c.c., with gum enough to make a syrup. With an oil immersion lens a film of normal blood treated with this solution gives red corpuscles stained yellow on a white or faintly yellow background. The white corpuscles are a faint lemon tint. Lymphocytes can hardly be distinguished. Eosinophiles are easily recognizable by their highly refractive granules and the polymorponuclear neutrophiles are distinguished by the darkness of their closely set granules. Masses of blood plates are often seen scattered about the films. These are the only elements in which there is normally the slightest trace of red or brown. This is typical "negative" reaction. In a "positive" reaction, the change occurs in the polymorphonuclears alone. The cells affected may give the brown color of glycogen in three ways: (1) As a diffuse coloration; (2) as fine granules scattered through the whole or part of the cell body; (3) as coarser granules or masses which are usually found at or near the periphery projecting beyond, as pseudopodia. The nature of the material so stained has been freely discussed, but there seems to be no doubt that it is not pure glycogen, but probably a combination of this with some other substance, possibly of a proteid character. From a clinical standpoint it is of great interest to recognize the condition under which this reaction may be expected. These are usually: (1) Severe disturbances of respiration; (2) anemia; (3) toxemias of metabolic origin; (4) suppuration and bacterial infection. The first three are chiefly of pathological and academic interest. Clinically the following are the chief conditions in which a "positive" reaction is constant. (*a*) Croupous pneumonia. Here the reaction is usually positive and intense. It often develops within ten hours of the initiative rigor. In the early hours of a central pneumonia it is of great diagnostic value. It persists until the crisis. If it does not disappear shortly after that event, the possibility of empyema is awakened. (*b*) In bronchopneumonia the reaction has been found, but is rarely so well marked. (*c*) In empyema the reaction is always positive. (*d*) In abscess and gangrene of the lung; (*e*) in septicemia and pyemias of all kinds; (*f*) in all advancing suppurative processes; (*g*) in appendicitis and peritonitis. In 21 cases of general peritonitis from various causes reaction is always present. In abdominal cases in particular, it seems to the author to be a much more trustworthy guide than leucocytosis, for while a high leucocyte count always indicates operation, many cases of appendicitis, as is well known, either have no leucocyte increase owing to the overwhelming of the organism by the virulence of the toxemia, or else show an increase of only two or three thousand above the normal. A most important point is the period after the onset of the symptoms at which the reaction appears. Locke found it faint three hours after the perforation of a typhoid ulcer. But it was well marked in the same case six hours later. The author has found it very intense twelve hours after perforation of a gastric ulcer, and fifteen hours after the onset of symptoms in a gangrenous appendix case; also well marked an hour and a half after the onset in an inflamed appendix and peritoneum. The relation of the reaction to leucocytosis may be briefly stated thus: While many of the causes which produce the reaction also cause leucocytosis, there is no necessary connection between the two. It is well seen in the case of rhumatic fever in which leucocytosis is the rule, the glycogen reaction, however, being absent. The glycogen reaction is more valuable as a diagnostic sign because it is not, as is the leucocyte count influenced by the extremes of the conditions which produce it. It is well known that there may be no leucocyte count in an infection of low grade or one of ultra virulence. It is probably the most delicate test yet found for indicating the presence of certain pathological phenomena.

Movements of Lymphocytes.—A characteristic property of leucocytes, as distinguished from lymphocytes, is their mobility and power to emigrate. If, however, subjected to abnormal conditions, lymphocytes will also give evidence of ameboid motion. When K. WLASSON and E. SEPP (*Virchow's Archiv*, Vol. 176, No. 2) heated blood to 42 to 48° C., the motions of the leucocytes became incoördinate and more than one pseudopodium was extended at the same time so that the cells often appeared very much elongated. Some of the cells became swollen and lost their vitality. The lymphocytes on the other hand were more active and at 440 they began to creep. If the temperature was reduced, the motion continued even down to 36°. If placental tissue, peptone or farina be added to blood the same changes are noticed at a lower temperature.

A New Alkaloid of Putrefaction.—By means of a complicated process, E. S. FAUST (*Arch. f. exp. Path. u. Pharmak.*, Vol. 51, Nos. 2 and 3) succeeded in isolating minimal quantities of a crystalline alkaloid, allied to cadaverine, from putrefying yeast. Injected into animals, it possesses the same action as yeast itself, hence is probably the cause of its intense toxic properties. The respiration of dogs will first be increased and deepened, repeated vomiting soon sets in and intestinal peristalsis is much stimulated. The animals seem to suffer from very severe tenesmus and soon pass pure blood. The respiration then becomes less frequent and the animals finally die in coma. At autopsy, an intense capillary hyperemia with ecchymoses, is the most prominent

feature. Emboli, however, do not occur. The action closely resembles that of arsenic.

Blood in Bilharzia Disease.—Being stationed in Egypt, A. Kautsky-Bey (*Zeitsch f. klin. Med.*, Vol. 52, Nos. 3 and 4) has ample opportunity to examine the effects of bilharzia infection upon the blood. It seems that the majority of patients, even of the better classes, are affected with this disease, the most prominent symptom of which is hematuria. As a rule the anemia is not excessive and is chlorotic in type since the number of red cells is relatively high. The eosinophiles are considerably increased. In many cases anchylostomum was also found in the feces, but these cases did not seem more anemic than the uncomplicated ones. Anchylostomum infection thus plays a very subordinate rôle in the etiology of Egyptian anemia as compared with bilharzia.

Granules of Leucocytes.—It is generally stated that the neutrophile and eosinophile leucocyte of the blood, together with the mast-cells, are the only normal granulated cells. A. Wolff (*Zeitsch. f. klin. Med.*, Vol. 52, Nos. 3 and 4) believes, however, that the lymphocytes and large mononuclear leucocytes possess distinct basophile granules which are, however, so easily dissolved out that often their vacuoles only are seen within the protoplasm. The ordinary neutrophile granules of the same person may take on different hues from blue to reddish-violet, but this is not sufficient reason to subdivide them, since, besides showing an affinity for the neutral dye, they also absorb varying amounts of the dissociated stains.

Anticrotalus Venin.—The investigation of the nature of the poison of snakes has always possessed a peculiar interest, due, in part, to the mysterious effect of an animal secretion upon other animals. This interest, which appeared to have culminated in the researches of Weir Mitchell and his followers and in the production of an antivenin by Calmette of Lyons, has been revivified by the impetus of the Ehrlich theory of immunization. It is upon this latter standpoint that the reinvestigation of crotalus venom was undertaken by Flexner and Noguchi (*Jour. Med. Research.*, May, 1904), with remarkably interesting results. Their problem was to produce an anticrotalus venom. Analysis showed them that rattlesnake venom owes its toxicity chiefly to a principle which they call hemorrhagin, which acts as a specific poison, a cytolysin on the endothelial cells of the blood-vessels. Hence, its local effect is primarily to produce profuse hemorrhage. This primary effect, coupled with other factors, such as bacterial invasion, rapidly leads to necrosis and putrefaction. In addition, however, the venom paralyzes the self-protective mechanism of the human organism—in terms of the Ehrlich conception, the venom amboceptor unite with and neutralize the human bactericidal complements. In order to produce an antivenom, two lines of procedure were tried. The attempt was made to attenuate the hemorrhagin by heat, but it was found that this modification destroys the active principle so that no antibody can be formed. The authors then determined to produce a toxoid, in other words, a molecule in which the toxicity is destroyed, while the power to set up antivenin formation in the rabbit and dog is retained. This they accomplish by subjecting the venom either to hydrochloric acid, or to the acid with pepsin, or to iodine trichloride. Thus the Ehrlich theory of toxins and toxoids proved of great practical value in obtaining a specific antivenin for the rattlesnake poison.

Complications and Degenerations of Uterine Fibromyomata.—The renewed interest which this subject has lately received, as applied to the question of treatment, renders of value a study of 280 cases of uterine fibromata made by E. McDonald (*Jour. Am. Med. Ass'n*, May 21, 1904) occurring during the last seven years at the Albany Hospital. An attempt has been made in this investigation to determine the frequency of the various degenerations and complications and to base on this certain conclusions concerning treatment. It appears from the study of these statistics that all fibroids which are producing symptoms, and all those designated as small (especially when subserous or intramural), should be removed, because the risk to the patient from operation is far less than that from the tumors themselves. In view of the sarcomatous changes, carcinomatous associations and complications, early removal is indicated when they are of sufficient size to produce symptoms. Small, uncomplicated tumors not producing symptoms do not require early treatment. Thorough pathological examination should be made of all fibroids for evidences of malignancy. Particular study should be devoted to those tumors which are necrotic, cystic or both, as among these are found the largest proportion of malignant changes.

Bile Capillaries of the Liver.—Under normal conditions the bile capillaries which run in the axis of a liver lobule unite to form an anastomosis of wide meshes and exhibit ampullæ where they meet. The intercellular branches generally end blindly but never reach the blood vessels; the branches that enter the cells themselves also enter blindly at some distance from the nucleus without giving off branches. In simple mechanical icterus, S. Abramow and A. Samoilowicz (*Virchow's Archiv.*, Vol. 176, No. 2) found dilatation of the entire system up to the finest branches, which elongate and often rupture so that the bile reaches the perivascular space. This is followed by necrosis of circumscribed portions of the parenchyma. Jaundice secondary to carcinoma and atrophic cirrhosis is only a variety of mechanical jaundice. In suppurative cholangitis the walls of the bile-capillaries are destroyed, which facilitates the discharge of bile into the perivascular spaces. In chronic congestion, solid matter is precipitated in the capillaries. The bile here reaches the lymphatic system owing to the obstruction caused by these thrombi and by the periportal connective tissue; besides this a destruction of cells goes on in the center of the acini owing to pressure of the dilated blood-capillaries; this will also destroy the contained bile-capillaries so that the bile can reach the lymphatics freely from the open ends.

Technic of Widal Reaction.—The various methods of performing the Widal test has been subjected to a comparative test by A. Lion (*Münch. med. Woch.*, May 24, 1904). He found the macroscopic test with living birth cultures rather uncertain, since it is difficult to obtain the proper turbidity of the fluid even if used after fourteen to twenty-four hours. Negative results were common where other methods were positive. The same observation was made when a loopful of an agar culture was rubbed up with saline solution, sometimes the agglutination was very imperfect though the case was an undoubted typhoid. Very good results were obtained with formalinized cultures; they keep for a long time and enable the busy practitioner who has neither time nor facilities to reinoculate daily, to use the test. A formalinized culture of typhoid plus paratyphoid has certain advantages, as it will react to either infection, though not completely so unless the serum has high agglutinating powers. Thus, in either typhoid or paratyphoid, the fluid will clear partly and on microscopical examination clumps and motile bacilli can be seen with this mixture, paratyphoid cases will no longer be over-

looked and a separate agglutination with each bacillus will decide which of the two is the cause of the clumping. The reaction with dead cultures is in every way as distinct as with live cultures, but is somewhat slower, so that the time limit must be extended beyond half an hour.

Relation of Some Other Bacteria to Typhoid.—An interesting and unique observation on the properties of some intestinal bacteria is put on record by E. Altschüler (*Münch. med. Woch.*, May 17, 1904). The Widal reaction in a case clinically presenting all the symptoms of typhoid was negative, but the paratyphoid bacillus type *A* was agglutinated in sufficiently high dilution. Blood obtained by venesection and grown on broth gave typical typhoid germs in pure culture and finally at autopsy the *Bacillus fæcalis alkaligenes* alone was found in the spleen. The only way the author could explain this case was by assuming that one germ only was present but that under different conditions it acquired different properties. To prove this, typhoid germs were grown on human placenta; after several months they grew on potato and litmus whey just like the *Bacillus fæcalis* and also lost their specific agglutination. A typical culture of *Bacillus fæcalis* was then allowed to stand for three months, and then transplanted and tested once a week. It gradually lost its typical character, and resembled more and more the typhoid germ; finally, after having been passed through a rabbit, very high agglutination toward a control typhoid culture was obtained. The altered typhoid germ again lost its newly acquired properties after three to four weeks, but the altered fecalis still resembles the typhoid in every respect after four months. The author found the fecalis most often in the stools of typhoid convalescents, rarely in milk and water and occasionally in normal feces. Its only two characteristic properties are its growth on potato and litmus whey.

Lecithin and Snake Venoms.—It has been proved by P. Keyes (*Hoppe-Seyler's Zeitsch.*, April 9, 1904) that lecithin is the chief activator for the amboceptors of cobra poison, since the latter alone is incapable of destroying red blood cells, but in the presence of minimal amounts of lecithin is capable of doing this. The author and H. Sachs also showed that these forms of blood that were laked by apparently cobra venom alone were really acted upon by a combination of venom and lecithin, since the latter is a constituent of the red blood cells and of the plasma. Now, although all kinds of blood contain lecithin, yet only certain forms are laked by cobra poison. This apparent contradiction is explained by the fact that lecithin is not bound up to an equal degree in all forms of blood. The method by means of which one may determine the strength with which lecithin is bound up with the rest of the cell, and which will enable one to peer into the recesses of lecithin metabolism, which method is afforded by cobra venom, is indeed a novel and promising one. Thus H. Sachs has shown that while cobra venom takes the blood of fetal cows, it has no effect upon that of the adult animal. He concluded that in the former the lecithin is held in loose union and is therefore capable of eliciting the toxic properties of cobra venom. This looser union of lecithin denotes a different degree of lecithin metabolism in the fetus, fortifying the generally accepted hypothesis that lecithin takes an important part in the development and growth of the organism. The author worked with a series of different snake venoms and studied their effect upon the blood of camels, oxen, rabbits, men, and guinea pigs. The blood of the first three was not affected, and of the last two, the blood was laked by different doses of the various poisons. These facts indicate that in different animals lecithin is bound up in varying degrees, and that in any one animal where blood is susceptible to the toxic influence of snake poison, the venoms of the different snakes have a varying avidity for the lecithin. In studying the effect of Calmette's antivenin, the author found that the protective influence of this serum varies in the same way with the different poisons and in the same order as these are capable of laking the red blood cells. These researches are valuable, apart from their own interest, for the light which they throw upon certain obscure problems in physiological chemistry, particularly upon the question of lecithin metabolism. These researches show at least that the lipoids are found in the organism, not free, but stored up in some chemical union.

The Toxic Characters of the Urine in Fatigue.—By injecting the urine of fatigued individuals into rabbits, G. Astolfoni and F. Soprana (*Arch. Ital. de Biologie*, March 24, 1904), were able to determine the variations in the toxic power of the urine under conditions of fatigue. They found that this toxicity is quite marked, and that a large part of the poisonous product elaborated in the organism during fatigue are rapidly eliminated by means of the urine, but that a small portion remains for some time in the organism. The latter fact is indicated by a miosis, which, although slight, persists for a long time, even after the other toxic properties of the urine have disappeared. These latter are seen in the marked tendency to produce convulsions, in an anti-diuresis, and in cases of prolonged fatigue, in direct fatal effects.

Histological Changes Produced by Adrenalin Chloride.—The increasing importance of adrenalin in hemorrhagic conditions and in cases of diminished blood pressure imparts a peculiar interest to the researches of W. B. Drummond (*Jour. of Physiol.*, May 3, 1904). The microscopical changes produced by this drug are to be attributed to its action upon the blood-pressure and to its toxic effects. The evidence of its action upon the vascular system is a congestion of the viscera and occasionally hemorrhages and serious effusions. The congestions due to the action of adrenalin upon the blood-vessels arise from an increase in pressure in the large arteries whose arterioles do not contract, or from a rise of pressure in the large veins, which increases the pressure in the central lobules of the liver and in the convoluted tube region of the kidney. The changes in the lung may be an edema or a congestion with or without hemorrhages into the air-vesicles. If the animal lives long enough the congestion is followed by inflammation due to effused blood or microorganisms. The author believes that the inflammation is also the result of a toxic action, as evidenced by early appearance of this phenomenon and the absence of microorganisms. He also agrees with Brodie, that adrenalin acts upon the peripheral blood-vessels through the vasomotor nerves. The experiments of Brodie and the author strongly contraindicate the use of this drug for hemoptysis. The toxic influence of adrenalin is manifested in the glandular organs, principally the liver and kidney, on which it acts as a protoplasmic poison. In the kidneys the brunt of this action falls upon the cells of the convoluted tubules, and in the liver upon the cells of the central zone. The changes in the liver are of marked interest in connection with the associated fall of urea nitrogen described by Patton.

Portal of Entry of Tuberculosis.—The old theory of infection by way of the respiratory tract is no

longer tenable, according to H. VOLLAND (*Münch. med. Woch.*, May 17, 1904). The real cause of tuberculous infection is scrofulosis which is common during the second year of life, since children then learn to walk and come into intimate contact with the dirt of floors and streets. Abrasions and eruptions about the nose and mouth, the epithelial desquamation incident to teething, all form ready portals of entry. Scrofulosis is thus due to dirt, and if tubercle bacilli are also rubbed in, consumption results. Prophylaxis should thus not be directed against adults, who are, as a rule, already infected, but against children before they learn to walk. It is very doubtful if a patient, who has passed through a tuberculous infection during childhood, will possess a protective degree of immunity during later life.

Intermittent Claudication.—The typical symptoms of intermittent claudication are given by W. ERB (*Münch. med. Woch.*, May 24, 1904) as follows: Paresthesiæ and pains in the feet on walking, tension, pain and stiffness in the calves or higher up, a cold sensation, anemia or cyanosis, sometimes heat and redness of the feet, difficulty on walking so that frequent rest must be taken. The most important objective sign is absence or smallness of the pulse in several or all of the arteries of the foot, with sclerotic changes in the vessels. In atypical cases there may only be weakness without the characteristic intermissions, but the objective symptom is always present unless there is an anomalous condition of the vessels, so that the blood-supply is normally insufficient. The disease is more frequent on the left than the right side, but usually bilateral. General arteriosclerosis is common, but the heart is usually found normal. There are cases where all the typical signs are present without lesion, since due to an angiospastic condition; conversely, all four pulses may be absent without symptoms. The majority of patients are males beyond forty years, of the better classes. The etiology is that of arteriosclerosis in general, but rather often a distinct history of excessive smoking can be obtained. The treatment calls for proper diet, iodides, heart tonics, the application of warmth and galvanic foot-baths.

New Method of Testing the Heart.—In a lengthy communication recently presented to the Verein für Innere Medizin, in Berlin, M. KATZENSTEIN (*Deutsche med. Woch.*, June 2, 1904) proposes a new method for determining the functionating power of the heart, which is particularly of service when that organ is about to be subjected to the strain of a surgical operation. His procedure is based on observations made on animals that ligature of the larger arteries results in an increased cardiac activity, which is characterized by higher blood pressure, without any change in the pulse rate. This condition does not disappear until the collateral circulation is fully established, and as the resistance becomes lessened after several weeks, there is a return to normal conditions. As applied in practice, the patient is placed in a reclining position, and when thoroughly quiet, the pulse rate and blood pressure are determined. Compression of both iliac or femoral arteries is then secured and kept up for two to five minutes, and then the changes noted in blood pressure and pulse rate. In a normally acting heart, the pressure causes a rise in the column of mercury of the instrument, of from 5 to 15 mm., while the pulse rate remains the same or is slightly diminished. In case of a hypertrophied heart, a rise of from 15 to 40 mm. is noted, and the pulse remains the same or is increased. A slight insufficiency is accompanied by a pressure of 0, and a pulse rate unchanged or increased. A marked insufficiency causes a minus pressure and an increase in the pulse rate. The method has the advantage of being simple and easily applied, and excitement being the only factor which might influence the result. This must be carefully guarded against.

Thoughts Suggested by Health Department Statistics.—Although statistics are seldom accurate, yet they furnish material for valuable deductions and serve to show the trend of various diseases. G. L. PEABODY (*Med. Rec.*, June 4, 1904) points out that since 1894 there has been a constant increase in the death rate, for typhoid fever, it having risen during that time from 4.37 to 11.26 per 10,000 inhabitants. One possible cause which he suspects is the fact of the deprivation of the excellent storage system for the drinking water which has been believed to be an important factor in purifying the water. It is now known that owing to the immense consumption of water, the water comes almost directly from the water-shed, and as it is impossible to absolutely protect that immense tract from pollution one must necessarily incur certain risks. The number of deaths from malaria—90—he believes to be impossible. No doubt, the majority of these were typhoid fever. A very satisfactory showing was made in smallpox, for only five deaths occurred. In commenting upon this disease he suggests that many unnecessary hardships to private families could be avoided if the rule of removal to quarantine stations could be more leniently enforced. If vaccination protects and thorough isolation could be carried out there ought not to be any more danger from the spread of this disease than from many others.

Demineralization and Tuberculosis.—A number of French authors have stated that hypo-acidity and a redúction in the inorganic constituants of the body, decreased the resisting powers of the organism against the invasion of tuberculosis and afforded a more favorable condition for the extension of the disease. F. STEINITZ and R. WEIGERT (*Deutsche med. Woch.*, June 2, 1904) have made a series of investigations in order to substantiate this claim, if possible. They made a chemical analysis of the entire body of an infant which had died from general tuberculosis and compared the results with those already known in healthy normal infants, or in those which died as the result of other diseases. It was found that the total amount of ash obtained from the tuberculous child about equaled that from the four months' infant which had died from ordinary gastro-enteritis, and therefore no marked demineralization appeared to have occurred. Lime, phosphorus, and magnesia were found to be lessened in amount, but this the authors attribute to the presence of a rachitis which was present in the tuberculous infant, but from which the other child was free. Potassium salts were unchanged and the sodium and chlorine elements were diminished. These findings apparently show that demineralization does not occur in tuberculosis.

Gastric Hemorrhage Due to Aneurism.—A fatal case of this unusual condition is reported by H. HIERSCHFELD (*Berl. klin. Woch.*, May 30, 1904) as having occurred in a young man of twenty-eight years, who was also a hemophiliac. During the course of seventeen years he had been subjected to hemorrhages from the stomach 13 times, and to the last of these he succumbed. At the autopsy the source

of the hemorrhage was seen to be a small miliary aneurism situated in the mucous membrane of the stomach, and this was surrounded by a number of varices, none of which had, however, ruptured. Evidences of an alcoholic gastritis were present, but the author thinks that the fatal bleeding would have been avoided if the man had not been a hemophiliac. The latter condition also prevented surgical interference, which would otherwise have been appropriate. The diagnosis of such cases would be difficult, but aneurism might be considered whenever repeated gastric hemorrhages are present without any pain. A purpose in reporting this case was to restrict the number of so-called parenchymatous hemorrhages from the stomach, which term has been employed to cover a number of obscure conditions.

PHYSIOLOGY.

Action of the Spinal Centers Upon the Tone of the Respiratory Muscles.—Because they are brought continually into action, the respiratory muscles possess a tone which is much more marked than that of the rest of the muscular system, according to A. Mosse (*Arch. Ital.. de Biologie,* March 24, 1904). The phrenic nerves exercise a tonic action upon the diaphragm. Asphyxia stimulates the nerve-cells in the spinal cord that govern the tone of the muscles concerned in breathing. These cells have an excitability of their own which is distinct from that of the other cells which innervate the muscles. When, by means of chloral, excitability is diminished and asphyxia is preduced, there occurs during the pause, when the violent respirations have passed, an increase in tone of the muscles of breathing, which is followed by the final respirations. The movements which are produced during the period of augmented tone, demonstrate that the tone of the muscles is quite a different thing from the ordinary contractions, since the two functions behave differently under the same conditions. When the animal is deprived of oxygen, the tonic respiratory centers in the spinal cord cease to act a short time after the cardiac inhibitory centers have begun to be excited. When the spinal cord has been paralyzed by cocaine, locally applied, and is beginning to recover, the first phenomenon to appear is the tone of the respiratory muscles, which shows that the functions of the spinal cord recover in the inverse order to their abolition. Moreover, the respiratory tone is not a constant one, but is subject to variations, resulting from changes in the excitability of the spinal cells. The tonic cells presiding over the thoracic muscles and diaphragm are independent among themselves and have distinct locations.

Changes in the Blood at High Altitudes.—An increase in the number of red blood cells (hyperglobulia) has been observed as the result of residence at high altitudes C. Foa (*Arch. Ital. de Biologie,* March 24, 1904), finds that this condition does not occur at the height of 1,200 meters, but that at 1,800 meters there is not only a rapid increase in the red blood cells within a few days, but also an increase in hemoglobin. At 3,000 meters the hyperglobulia begins eight to nine hours after arrival or even sooner. It varies in degree with different individuals. Hemoglobin increases *pari passu* with the red blood cells. The hyperglobulia is merely peripheral, being absent in the blood of the larger arterial trunks. In experiments performed upon rabbits and guinea-pigs the author noticed that six hours after arrival at the altitude of 3,000 meters and from one to six days of residence at 4,560 meters, the bone marrow does not show, either by its color or by its microscopical appearance, any increased hematopoxesis. The latter, however, occurs from eight to twelve days after arrival at the higher altitude. In individuals, on the tenth day of residence at high altitude, there is a slight increase in red cells and hemoglobin even in the large arterial trunks, which is the result of increased production of erythrocites in the red bone marrow. Thirty-six hours after a return to the sea-level, the peripheral hyperglobulia has disappeared. The climatological and therapeutic applications of these researches suggest themselves.

The Causes of Peripheral Hyperglobulia at High Altitudes.—In conducting a critical and experimental research into the cause of the increase in the number of red blood cells in the peripheral circulation that ensues upon residence at high altitudes, G. Foà (*Arch. Ital., de Biologie,* March 24, 1904), finds that upon the returning of the blood to its normal condition when the individual returns to the sea-level, there is urobilinurea, which indicates that there is no destruction of red blood cells. Grawitz has sought to explain the increased erythrocytosis upon the basis of a loss of the fluid elements of the blood; but the author finds that the body actually exhales less water in a rarified atmosphere than in a normal one. The author believes that the principal erythrocytosis of high altitudes is to be attributed to a stasis of blood in the dilated superficial vessels, so that the red corpuscles. being the heaviest morphological elements, circulate least rapidly, and loiter in the capillaries.

The Behavior of Carbon Monoxide in the Organism.—The manner in which carbon monoxide is eliminated from the body is, according to P. Giacosa (*Arch. Ital., de Biologie,* Vol. 50, No. 2) not yet perfectly known. It has been found that in an animal which has survived intoxication, however severe, after a variable period of time, the blood does not contain carbon monoxide hemoglobin. This disappearance does not take place if the blood after removal from the body is hermetically sealed, or if it be allowed to remain in the cadaver; the disappearance of this compound is therefore bound up with phenomena connected with life. The author was able to prove that CO hemoglobin decomposes when exposed to the air for a long time. The question arises whether carbon monoxide leaves the blood without suffering any change, or whether it is oxidized into carbon dioxide. Has the living organism the power to oxidize the molecule CO into CO_2. The prevailing opinion has been that the latter is the case. Experiments have been conducted to determine whether the disappearance of CO Hemoglobin from the blood is associated with the appearance of CO in the expired air, and the results of various investigations have been contradictory. On this subject the author performed certain preliminary experiments. He found that the blood obtained from an intoxicated animal, or healthy blood which has been impregnated with CO, and then defibrinated in either case, if kept in test tubes in a water-bath at a temperature of 38° C., gives off CO for several hours, at first with intensity, which diminishes until at the end of fifteen or sixteen hours there is not a trace of CO in the air emanating from the surface of the blood. The author then studied the possible effect of fresh pulmonary tissue upon this liberation of CO. At first this is retarded, but later on there is an increased elimination of CO. Moreover, the blood containing pieces of lung becomes cloudy, and putrefies after a number of hours, while the plain blood does not putrefy. The author now performed an experiment to see if CO_2 may be produced in the blood at the expense of CO. He found

that blood containing carbon monoxide and pieces of lung produced more carbon dioxide that either healthy blood with pieces of lung, or blood with carbon monoxide alone. This result proves that CO is really oxidized into CO_2. The author revealed a further fact, which may possibly be of service in the treatment of cases of carbon monoxide poisoning, namely, oxygen, particularly at an elevated pressure, facilitates the dissociation of and expels from the blood every trace of carbon monoxide.

SURGERY.

Treatment of Fractures.—In order to avoid the difficulties and uncertainties of the bloodless reduction of the fragments in a fracture of the lower end of the humerus, P. Niehans (*Archiv f. klin. Chir.*, Vol. 73, No. 1) proposes the temporary fixation of the fragments with steel nails. He has found the procedure of particular value in children. The operation consists of an exposure of the parts which is secured by reflecting backward, the mass of extensor muscles together with the olecranon process, which has been temporarily resected. The fragments are then brought into apposition and held in place by two steel nails, of a square form and nickelplated. The latter may again be removed in from four to seven days. The fragments will have become sufficiently united to permit fixation of the arm in an ordinary sterile dressing. The osteoplastic ulnar flap heals like any other sutured olecranon fracture. The writer has also treated in a like fashion, fractures of the greater tubercle and the head of the humerus. Six successful cases are reported, and it is suggested that the method might also be applied to condylar fractures in the knee-joint, fractures of the tibia, astragulus, etc.

Appendicitis and Inguinal Hernia.—An interesting study is presented by M. A. Wassiljew (*Archiv f. klin. Chir.*, Vol. 13, No. 1) of 63 cases of appendicitis which have developed in the hernial sac in males. He reports in detail his own case, the others are gathered from the literature. Infancy and old age offer the main predisposition to the condition. This form of appendicitis may assume the acute or the chronic type. The acute form rarely runs such a stormy course as that in the free abdominal cavity, and even where perforation has taken place, it often assumes the subacute form. The diagnosis is almost impossible to make, but the prognosis is more favorable than for the condition in the abdomen. The operative treatment must be directed toward both conditions, but the corrective treatment of the hernia itself depends more or less on attendant circumstances. In 39 cases where resection of the appendix was done, there were only three deaths, while in 18 cases where this was omitted, ten deaths occurred. An endeavor should be made to save the testicle, but in chronic cases with much tumefaction castration must be resorted to.

External Luxation of the Knee.—If one should judge by the number of reported cases, this lesion must be looked upon as an exceedingly rare one. Vautrin (*Rev. de Chir.*, April, 1904), states that in his opinion external luxation is more common than ordinarily supposed. If this be true, the frequent complication of the lesion by tearing of the external popliteal nerve renders the lesion of very considerable surgical importance. The author states clearly that he does not refer to external dislocations of the knee, which must, in the nature of affairs, be produced by profound traumatism. It is the milder forms, the luxations proper, which he discusses. In reading the old observations of Malgaigne, Hamilton and Claudot one reaches exactly the same conclusions, viz., that this form of traumatism is accompanied by an almost infinite variation in the degree of traumatism both to the soft and to the hard parts, that sometimes reduction is remarkably easy, sometimes impossible without an anesthetic; that immobilization after reduction does not justify one in counting upon complete functional success; that, all in all, no conclusions as to the degree of internal injury can be reached with the ease or difficulty by which reduction has been accomplished. It is a mistake to believe that cure lies entirely in the reëstablishment of the ligamentous portions of the joint. The restoration of the crucial ligaments or the attachment of the cartilages does not always depend upon a prolonged immobilization. This serves to add importance to the question whether one should or should not immobilize the parts for a long time. Since so little of the actual conditions prevailing in the joint can be determined from physical examination, obviously no dogmatic conclusions can possibly be reached which will apply to this form of injuries. The luxation of the fibula is one of the most important considerations in determining the treatment, because of the anatomical relation of the external popliteal nerve to the head of this bone. The duration of immobilization varies, of course, with the gravity of the case. If the fibula has remained in place, three weeks will usually accomplish all that may be necessary. But should this immobilization be blindly conducted, the dangers attending it are possible anchylosis and loss of invaluable time, which might have been devoted to the remedy of nerve defects had such been ascertained by open incision and repaired at the time of replacement. The injury to the hard parts is often complicated by repairing of the vascular supply of the joint. Although the destruction of the veins is of serious import, it does not compare in gravity with the rupture of the artery. This, as is well known, results always in a traumatic aneurism which often terminates in gangrene. The injury to the nerves has been but slightly touched upon by surgical authors. Eames has reported a single case which was complicated by complete paralysis of the anterior tibial nerve resulting from an anterior luxation of the knee with fracture of the tibia. The author then cites the history of a case of a young soldier, who in jumping on a tanbark court, twisted his knee, luxating it externally. He was unable to see the patient until twenty-four hours was passed. The fibula was also dislocated. Disability was complete. Pain was marked over the popliteal space, but both the popliteal and the tibial arteries pulsated normally. Under chloroform anesthesia the luxation was reduced without trouble. The injured member was immediately immobilized in complete extension. Very shortly after the replacement, it was noticed that all muscles were paralyzed, which were supplied by the external popliteal nerve. Sensation of the perineal region was also almost nil. It was thought at first that this was due to a simple compression, but after a few days it was found that despite the subsidence of the hematoma, the paralysis remained. Electricity, massage and all forms of treatment were resorted to, but for three months there was no change. Walking became very difficult. The point of the foot was dropped, unusual motions of the body being necessary to raise the member in stepping forward. Operation was advised, but was refused. It is not surprising that the external popliteal nerve should be torn if the external ligaments are ruptured. Indeed, the anatomical arrangements of the parts are such that it seems difficult to believe that any extensive ligamentous tearing may take place without corresponding injury to this nerve. The author therefore advises that in all these cases the nerve should be freely exposed and sutured if necessary.

SPECIFICITY IN BACTERIOLOGY.

Among the many important contributions of Koch, there are few which have had a more notable influence in the development of bacteriology than his theory of the specificity of micro-organisms. Men have come to regard this theory as almost an axiom of biology, and thus underestimate the tremendous advance which it marked in the progress of medicine. That bacteria are definite species, with definite biological and, under given conditions, definite pathogenic characters, seems to be a fact so self-evident that those who would doubt it carry the burden of disproof.

Not so in the sixties and seventies of the preceding century. At that time the theory of Pettenkofer in Munich was dominant, who held that in the bacterial world there was no fixity of specificity, either from a biological or a pathogenic standpoint. It was then commonly taught that harmless micro-organisms might, by a period of sojourn in a proper environment, become endowed with the virulence of a typhoid or a cholera germ; the fixed quantity in the etiology of disease was the soil, not the germ. All this was changed by Koch, and, with it, the etiology of modern medicine.

Many onslaughts have been made on this theory, and it has weathered them all. Experimental work has revealed the fact that there is hardly a characteristic of the bacteria which cannot, by artificial conditions, be markedly altered; reducing forms may be made non-reducing, sugar-fermenting forms trained not to ferment, and pathogenic traits may be "attenuated" out of existence. And yet these striking metamorphoses have evinced themselves as nothing but masks, as a change of complexion, under which lay concealed the original type in its pristine character.

Nevertheless, it may now truly be said that the fate of the theory has become seriously imperiled. The story is not a very long one. In October, of 1903, a case of a supposedly typhoid infection appeared in the wards of the Naunyn clinic in Strassburg. As is the practice in that clinic, the agglutinating reactions were immediately tested with formalin emulsions of the typhoid, paratyphoid A, and paratyphoid B, stems. It was found that the reaction was marked for the paratyphoid A, and weak for the others. With the view of further investigating this rare disease, paratyphoid blood cultures were taken. To the great surprise of the bacteriologists, not paratyphoid A, but typhoid bacteria were grown from the blood. This, however, was not all. The patient died, and from an abscess of the spleen a pure culture of a third species, *B. fæcalis alkaligenes*, was grown. Here was a problem: Was the case one of a triple mixed infection? Or was it a case of heteromorphism of one and the same organism? The latter hypothesis has been exploited by one of the assistants of the imperial typhoid commission in Strassburg, and with truly remarkable results. He discovered that by growing typhoid bacteria over many months on sterile placenta, he could change its biological characters to such an extent that it became indistinguishable from *B. fæcalis alkaligenes*, while, on the other hand, the latter organism could by other manipulations, the details of which must be sought in the original, be transformed into an apparently genuine typhoid form.

Was there here a true or only an apparent and superficial metamorphosis? There are still other tests, which are commonly believed to be far more crucial and distinctive of a micro-organism than its biological characters, namely its pathogenicity and, in still higher degree, its agglutination reaction. The altered forms, or "sports," should be examined by these criteria. And here is the crowning detail of the entire research—the bacillus of typhoid had lost enormously in its patho-

genicity and in its susceptibility to immune serum, and the fæcalis had gained in a corresponding degree. Apparently the typhoid had become a fæcalis, and vice versa. There is no other way of describing the results.

This is the most striking and clear-cut contribution which has ever been made to the problem, but it does not stand alone. There is a constantly increasing fund of data which goes to show that biological characters, pathogenicity, and agglutinability of any form may be considerably altered by external factors, and that, having been so altered, they may retain their new characteristics as fixed traits apparently over indefinite periods of time. Especially noteworthy are such researches as that of Buxton and Vaughan, which demonstrate a high degree of instability in the agglutinating function, and its permanent reducibility in the typhoid germ. The evident trend of all these currents is towards a reversal, or a modification, of the theory of bacterial specificity as advanced by Koch. To go no further than the typhoid problem, it becomes pertinent to inquire whether every sporadic case of typhoid must necessarily be supposed to have derived the contagium vivum from a previous case. As Altschüler suggests, it is at least imaginable that that ordinarily harmless denizen of the gut, the *B. fæcalis alkaligenes,* may under circumstances of growth, not as yet understood, become pathogenic—become, in fact, a paratyphoid or a typhoid organism. The hypothesis five years ago would have seemed worse than heretical, but seems now almost unavoidable. And if this be admissable, it seems pertinent to inquire into the status of the pseudo-diphtheria bacilli, the pseudo-tubercle forms, and a vast number of other organisms, and their relation to the so-called "true" agents which they simulate. All this is, indeed, very hypothetical, and very unorthodox, but it is at the end of the vista which has been revealed by the researches of the past few years.

A MODERN DIDO.

Psychologists teach us now that crime, like disease, comes in epidemics, and that waves of deviation from the normal standard are apt to sweep communities at stated times and intervals. Some particular form of depravity or mental aberration becomes rampant, and from its frequent occurrence attracts widespread attention, only to subside as some other manifestations of "undivulged crime, unwhipped of justice," takes its place. Thus the public mind, particularly that of the professional reformer, is led to the erroneous conclusion that mankind is degenerating and that there is now little to be saved from what Addison was pleased to term the wreck of matter and the crash of worlds.

The latest illustration of the contagiousness of a bad example may be found in the number of deaths, by suicide, that have been reported in the newspapers from all parts of the country. Now suicide is not a new development and it has existed from time immemorial in all countries and among every condition of men. At least three European monarchs are known to have taken their own lives during the last hundred years, one of whom, the late Sultan of Turkey, Abdul Assiz, became Abdul As-*was,* through the medium of a convenient pair of scissors. Added to these are at least a dozen princes of the blood, the more prominent of whom perhaps was Prince Gaston of Bourbon, the son of the late King of Naples, who was married to the Infanta Isabella of Spain, and who cut his throat in the presence of his wife. Other notable instances of self-destruction are those of Gen. Sir Hector MacDonald, the late Duke of Bedford; Count Wolkenstein, the Chamberlain of the Court of Vienna; the Marquis of Londonderry, the Earl of Munster, the Spanish Duke of San Carlos, Grand Chamberlain to King Alphonso; the Marquis Rappolo, stepfather to Queen Marguerite of Italy, Baron Bruck, the Austrian cabinet minister, and others too numerous to mention. The saddest case of all perhaps was that of gallant old General Bourbaki, one of the greatest heroes of the Franco-German war of 1870, who attempted to blow his brains out when the raw and untrained conscripts intrusted to his command fled *en masse* across the Swiss frontier. Luckily he recovered from the severe self-inflicted wound and lived for many years, as his biographer states, honored both at home and abroad as a particularly gallant and splendid specimen of the old French soldier.

Up to the present time, however, the inhabitants of the United States seem to have found their lot a happier one than the subjects of the European Powers, though if the reports in the newspapers can be trusted, we seem now to be running them a very close second. Thus we have had more than one case of hara-kiri, with a strict adherence to all the details of the Orient. While the "happy despatch" has been busy with the unhappy denizens of the Mongolian washhouse districts. Even the naval service of the

United States has not proved exempt, and the rule of three was sadly exemplified in the ward-room of one government ship alone.

We have had deaths by drowning, by the use of the pistol, with the poisoned cup, by cold steel, and now, as a culmination, we are brought face to face with the self-attempted taking off of Mrs. Sarah Montgomery, of Elton, Ind.

Mrs. Montgomery was a woman, and, therefore, to be wooed, and, having been won by love's insidious charms she seems to have been possessed of its sweet unrest to a degree to change its rosy hues to the jaundiced green of jealousy, and being no longer able to fear the ills she had she determined to fly—or rather steam—to those she knew not of.

But the conventional methods of suicide must have seemed to her commonplace and out of date, for in her attempt to shuffle off this mortal coil she did not follow suit, but trumped in with an originality that was all her own. Procuring a quart of gasolene she quaffed it at a single draught, and then applying a lighted match to her vapor-laden breath she surrendered herself to a Didonian, but an internal pyre of flame.

That she was sadly hurt is only natural, but let us hope that the one fire will burn out the others burning, and that when she emerges from a speedy convalesence that she will have forgotten the incendiary spark from which so great a conflagration came. At all events she can console herself in this, the hour of her affliction, with the comforting realization that she, too, has established a "record" and one that she is likely to hold in unchallenged security, of being the first and only person to make a practical, if unsuccessful, attempt to fire off the cannon that Hamlet tells us the Everlasting has fixed against self-slaughter.

ECHOES AND NEWS.

NEW YORK.

Dentition and Epilepsy.— Dr. Wm. P. Spratling, Superintendent of Craig Colony, Sonyea, N. Y., is anxious to collect information bearing on the influence of the first dentition periods, from the 6th month to the end of the first year, on the production of convulsive seizures, epileptic and non-epileptic.

Beth Israel Training School.—The graduating exercises of the nurses of this school were held in Clinton Hall July 12, 1904.

Tuberculosis Hospital on North Brother Island.—Health Commissioner Darlington has advertised for bids for the building of a "rest cure pavilion" on North Brother Island. The pavilion is needed as an adjunct to the hospital for consumptives which has been established on North Brother Island.

Pneumonia Investigation and Prophylaxis.—The Board of Estimate appropriated $10,000 last week to pay the expenses of a commission of medical experts to pass on the question whether or not pneumonia is a contageous disease. The appropriation was asked for by Health Commissioner Darlington, who showed that, although pneumonia is generally regarded as a complaint only prevalent in the winter, the number of deaths from this cause have been unusually numerous this year, and the cases have also been confined to particular localities. The inference Dr. Darlington has drawn from his observations is that the disease may be contagious. Before going to the expense of disinfecting houses in which deaths from pneumonia occur, however, Dr. Darlington suggests that an expert commission be appointed to study acute lung diseases, and especially pneumonia, with a view to ascertaining how such diseases are communicable.

Summer Corps Work in Brooklyn.—Officials of the Health Department in Brooklyn are making a determined effort to decrease the mortality among infants in that borough this summer. Nineteen physicians have been placed on the summer corps of medical inspectors, which is nearly twice the number ever before employed. Particular attention is being paid to the milk supply. Last week the inspectors started out to test all the milk that is being offered for sale in the stores. Their orders were to take the temperature of the milk, and if it is above sixty degrees it is to be condemned. The cans are to be hermetically sealed, the Health Office notified, and the permits to sell milk will be cancelled at once. Dr. E. P. Harman has been placed in charge of the summer corps, and he has apportioned the men so that the crowded sections of the borough, where the infant mortality is the greatest, will receive the most attention. Seven nurses have been assigned to this part of the work, and the mothers will be instructed how to feed and dress the small children during the warm weather. Impure and improperly cared-for milk is believed to be the greatest cause of death, and for this reason particular attention will be paid to the milk supply. The milk will be tested at frequent intervals and special precautions will be taken during the exceedingly hot weather. It was for the purpose of making this part of the work more thorough than it has ever been before that the medical inspectors who had been employed in the schools were kept at work during the summer months.

PHILADELPHIA.

Improvements at Hospitals.—Extensive improvements are soon to be made at both the Presbyterian and German hospitals. At the former will be erected a four-story brick maternity building; the latter will make alterations and additions costing $20,000.

Sale of Liquor by Druggists.—The internal revenue collector in this city, in answer to complaints, has received word from the federal authorities that it is a misdemeanor for Druggists to sell spirituous liquors as such, without adding anything to make of them a medicine. The complaint originated from the selling of whiskey and the like on Sunday. Wholesale druggists believe the federal government has no right to interfere with druggists who are allowed by the state to sell pints of whiskey on physicians' prescriptions.

Relatives to Support Insane.—Philadelphia has made a move in the effort to compel certain persons to support at the Norristown asylum friends or relatives who have hitherto been supported by the city. Twenty-one persons have been summoned to court on July 26 and many other cases are being investigated. It has recently been found that the city is paying thousands

of dollars that should be paid by those who are fully able to do so.

Filtered Water for West Philadelphia.—It is announced that in four weeks every part of West Philadelphia will be furnished filtered water. For some time past that part of the city has been receiving a mixed supply.

CHICAGO.

Appointment of Dr. Croftan.—Dr. Alfred C. Croftan has been appointed physician-in-chief to St. Mary's Hospital; and Dr. A. J. Ochsner, surgeon-in-chief.

Fatalities Due to Lockjaw.—There have been seven deaths reported to Coroner Traeger as the result of accidents sustained on the Fourth of July by celebrators. All of these cases of tetanus were attended by much suffering.

Reduced Infantile Mortality.—To save the lives of the children of Chicago's poor, the Milk Commission of the Children's Hospital Aid Society has begun its summer campaign. Through the work of the Commission last year in supplying pure milk and educating mothers to give their babies proper diet during the hot months, the infantile death rate was reduced, and this year the work of this new philanthropy will be carried on with greater energy and upon a larger scale. The coming of Dr. Lorenz to Chicago first called public attention to the fact that comparatively little was being done for the sick and crippled children of Chicago. A public call sent out from the Chicago Woman's Club resulted in the organization of the Children's Hospital Aid Society, which was incorporated in January, 1903. Distribution of 223,200 gallons of milk was the great work accomplished last summer between July and November, and this with only six persons paid for their services. Strained, filtered, Pasteurized, sealed in bottles and distributed to thirty-five stations maintained throughout the city, and all done within twelve hours from the time the milk is furnished by the Jersey herds in Wisconsin, this systematic charity work presents features of organization more complete than evidenced in any other undertaking for the benefit of the city's poor. The milk is sold in various modifications, the aim being to render it in all cases as near the strength of mother's milk as possible. Modification No. 1 is suited to young babies, with an increasing strength ratio up to the whole milk, suitable for older children, adult typhoid fever patients, or other invalids desiring and needing a fresh, pure, wholesome milk. The charges made for the modifications are all nominal and very low. Modification No. 1 sells, in a three-ounce bottle, sufficient for a single feeding of a young child, for one cent. No. 2 comes in a six-ounce bottle for 2 cents. No. 3 has a similar valuation. An eight-ounce bottle of No. 4 calls for a payment of 3 cents, and No. 5 costs the same.

Work of Children's Aid.—The first work undertaken by the Children's Hospital Aid Society was a thorough investigation of Chicago's facilities for caring for sick and crippled children. It was found that out of the 27 city hospitals visited, children's wards were maintained in only 18; the total of 320 beds thus furnished included the resources of the Home for Destitute Crippled Children. Only one Chicago hospital, the Maurice Porter, is devoted exclusively to children, and the only two places of refuge for children afflicted with infectious diseases may be found in the Memorial Institute, maintained in connection with the Presbyterian Hospital by Mr. and Mrs. Harold F. McCormick, and the City Smallpox Hospital at Dunning. Children suffering from infectious diseases must still be sent to Cook County Hospital or to the Dunning Infirmary unless eligible for one of the ten beds, exclusively retained for scarlet fever patients, of the Memorial Institute. The work of the Children's Hospital Aid Society during its first year and a half has resulted in greatly improved conditions, and in all hospitals at present maintaining no children's wards the little ones are to be received shortly. Eight old-fashioned and not altogether perfect wards in other hospitals are to be rebuilt or replaced by the pavilion system.

Officers and Directors.—The officers and directors of the Society are: President, Dr. Frank Billings; Vice-President, Mrs. Geo. W. Plummer; Secretary, Mrs. Harold F. McCormick; Treasurer, Mr. E. T. Keith; Directors, Drs. John Ridlon, and W. S. Christopher, Judge O. N. Carter, Mrs. W. P. Henneberry, and Mr. Medill McCormick. The Milk Commission is headed by E. P. Bicknell, of the Chicago Bureau of Charities, with Mrs. George M. Moulton as managing director, and Dr. Frank Billings, Miss Fulmer, Dr. Isaac A. Abt, Mrs. Geo. W. Plummer, and Mr. Medill McCormick to complete the Committee.

Hospital for Children.—Some time in the near future the Society hopes that a special hospital for children, with long-needed improvements in the facilities for treatment of chronic child invalids, crippled and mentally defective children, and public school children in need of the eyeglasses their parents lack means to provide, may be brought into existence in Chicago. But for the present its efforts are generally directed to ameliorating prevailing conditions. The education of the poorer portion of the public must come first of all, in the opinion of those who know whereof they speak.

Chicago Milk.—During a period of about two months covered by his reports, Professor Jordan, of the Bacteriological Department of the University of Chicago, found that about 31 per cent. of the 291 samples of milk examined by him were below the city standard in respect of total solids. During the same period the findings of the Municipal Laboratory indicated a quality of milk just about four times as good. The Chicago *Tribune*, in commenting on the milk question, has this to say: "Were the city inspectors four times as fortunate in the samples of milk which they happened to collect? Was Professor Jordan four times as rigid in the use of alkaline tablets, nutrient gelatines, and Quevenne lactometers? Or does the habit still survive among the city inspectors of taking a pleasant little morning drive in their municipal buggies along the boulevards, and of incidentally picking up a few samples of the superior kind of milk which is served to boulevard customers? Whichever of these questions may touch the right spot, it remains true that a discrepancy exists which, out of regard for the health of Chicago, ought to be explained. Is our milk as rich as the city inspectors think, or is it as thin as Professor Jordan's laboratory indicates? And, further, should not the city, as soon as it can afford to do so, provide for an inspection of milk not only with regard to its percentage of total solids, thereby establishing its nutritive value, but also with regard to its bacterial inhabitants, to prevent the spread of disease through milk."

Milk Fund Too Small.—Bacteriological tests of milk are made as regularly as possible with a small staff of inspectors and bacteriologists, according to Health Commissioner Reynolds, who thinks the Health Sanitation Committee of the Civic Federation, in its recent criticism should have taken into account the small appropriation for inspection. The Committee secured tests of 291 samples in two months, and found many of them below grade with regard to butter fat and solids. That four times as much milk escapes supervision as is tested is considered an exaggeration when

based on the investigation of 291 samples, but Dr. Reynolds considers that some milk is bound to escape the inspectors because of the small staff of men given him to work in conjunction with the City Laboratory.

Pamphlet on Tuberculosis.—The Illinois State Board of Health recently issued a pamphlet written especially for the laity, and intended for distribution broadcast, in which consumption is described, its ravages clearly pointed out, and rules for its prevention and limitation of its spread detailed. The State Board of Health announces that it will make free examinations of sputa in needy cases.

GENERAL.

Honor for Dr. Osler.—Dr. William Osler was one of the four who received the degree of LL. D. at Harvard this year. President Eliot pronounced him "the leading medical consultant author, teacher and orator of this continent."

Cholera Epidemic in Persia.—There is an epidemic of cholera in Teheran, Persia, according to a dispatch from there on July 8. The deaths number several hundreds daily.

X-rays in Leucemia. —A dispatch from Turin dated July 11 states that Dr. Bozzoli, director of clinical medicine at the Turin University, has informed the Academy of Medicine that experiments he has made have shown that the X-rays have remarkable efficacy in some serious diseases of the blood. He says that he has cured by this means a supposedly incurable case of leucemia.

Model Field Hospital.—The army hospital detail which left Washington a few days ago for Gettysburg to participate in the encampment of the National Guard of Pennsylvania, is a thoroughly equipped outfit. The detail consists of ninety-two men, including two officers, and is intended to serve for educational purposes. The company took a model field hospital of 108 beds, which will be set up at Gettysburg. It includes operating rooms, laboratory, diet kitchen, and acetylene gas plant for allumination, and all its departments and rooms will be connected by electric bells. It is said to be the most complete field hospital ever erected, and its demonstrations will be of great service to the medical officers of the National Guard. The hospital is in charge of Assistant Surgeons H. L. Gilchrist and Charles B. Reynolds.

Morristown, N. J., Medical Society.—At a meeting of this society July 16, some definite action was taken relative to payment for professional services. One of the members present is quoted as saying: "I want it especially impressed on the people that we are going to have a blacklist, and those persons who do not pay their medical bills will have no attention paid to their calls for aid. This is merely a matter of protection. There are many persons who call in a different physician every time a case of sickness occurs, and never pay any bill. That is not right. Those who want medical attendance should be willing to pay for it, and if they will not pay willingly, then they should be made to pay. Our list will put a stop to most of the deadbeat business." Dr. H. M. O'Reilly is President of the society.

New Jersey State Medical Licentiates.—At the meeting of the State Board of Medical Examiners held at Long Branch, July 5th, the following candidates for a State medical license, who passed the examination at Trenton on June 21-22, were licensed: Edward John Beardsley, David Fuller Bentley, Norman Sinclair Betts, Louis Nicholas Blank, Guy Otis Brewster, Frank Halstead Brown, Hayes Joseph Burnett, Charles Lawrence Constantinides, Frank Bacon Cook, Henry Augustus Craig, Percy Edward Dèckard, Lawrence Daniel Doyle, Lancelot Ely, James Ferrier, Albert Ferdinand Garton, Samuel Greenburg, Isaac Norwood Griscom, Kenneth Sylvan Guthrie, Clement Jacob Hailperin, Harvey Whesley Hartman, Walter P. Evans, Ephraim Clark, Charles Albert Knox, William Paul Lamb, Charles Jacob Larkey, John Joseph Magner, Harry Ross North, Harry Zebulon O'Brien, Homer Tomlinson Partree, Frederick Marshall Paul, Charles Blaine Piper, Henry Stanley Riddle, William Frederick Ridgway, Joseph Potter Riggs, Walter H. Smith, Lester Hevlyn Sparks, Newton Henry Stein, Louise Martha Sturtevant, Walter Albert Taylor, Henry Woodbridge Thayer, William H. Wells, Stephen S. P. Wetmore, Herbert Willis. The following attained the Honor Roll, or a general average of 90 and upwards: Dr. Louise Martha Sturtevant, A.B. of Wellesley, and M.D. of Boston University School of Medicine, attained 91.6; and Dr. Henry Augustus Craig, M.D., of Columbia University, attained 90.7. The following officers were elected for the ensuing year: President, Dr. William H. Shipps, Bordentown; Secretary, Dr. E. L. B. Godfrey, Camden; Treasurer, Dr. Chas. A. Groves.

Race Suicide and Education.—Under caption of the "College Girl and Race Suicide" the *Sun* speaks editorially on the contention that college women do not marry. It says: "The college girls, or rather former college girls, of the country are up in arms. They resent in particular the statement made recently in a New York medical journal to the effect that American women are too highly educated; that it is because of this that they are failures from the point of view of maternity, and, finally, that 'as women's mental powers increase, their bodily powers decrease.' It is obvious that the case that certain persons try to make out against the college women in particular must fall to the ground if it can be shown that a larger proportion of them are healthy, marry and have families than is the case with their sisters who never went near Vassar, Wellesley, Bryn Mawr, Barnard or Radcliffe. It would be no more absurd to attribute the low average birth rate of Kalamazoo or Oshkosh, if they have a low birth rate, to the fact that the owners of apartment houses in Manhattan and Brooklyn don't like tenants with children, than it is to say that the reason women who have never been to college don't have large families is because Greek and mathematics and modern science have knocked thoughts of marriage out of the heads of some college women. The fact remains that the average college woman is just as feminine as her sister, and if she is just as feminine she cannot be without the tendency to regard man, not as an enemy, a negligible quantity or an inferior animal, but as something very much more important than a necessary evil."

To Keep Mosquitoes Out.—In carrying out its plans for the sanitation of the Panama Canal Zone the Isthmian Canal Commission will shortly advertise for bids for 100,000 yards of wire netting with which to screen the various buildings along the line of the canal, so as to protect the officials and employees from the mosquitoes, which carry yellow and malarial fever. This will be probably the largest single order of wire screening ever placed. Experience has shown that ordinary wire screens do not last more than six months in that moist climate, and Gov. Davis of the Canal Zone has recommended the use of galvanized steel, brass or copper wire, which will be much more durable. The work of sanitation now going on under the direction of Dr. Gorgas includes not only a general cleaning up of the towns and villages, but a systematic anti-mosquito crusade. Ponds and pools of standing water are being covered with kerosene, etc. Work has also begun on the drainage of swamps and like mosquito breeding places

in the zone, which will require something like a year to complete. So far there have been but few cases of yellow fever and but one American has died from the disease.

Professor Koch and the Royal Commission.—The *Sun* expresses its views on this subject as follows: The question whether or not tuberculosis can be transmitted from animals to man is obviously of immense importance to all those interested in the question of public health, especially in the great cities. Prof. Robert Koch, who succeeded Virchow as member of the Berlin Academy of Science and who has been for some time director of the Prussian Institute for Infectious Diseases, is the leading authority in Germany to take the negative view. He holds that there is no connection between human and animal tuberculosis. Some time ago the Prussian Government appointed a Royal Commission to inquire into the subject. When its ad interim report was published the other day Prof. Koch was absent from Berlin. The experiments carried on by order of the Minister for Public Instruction seem to have been inconclusive. Prof. von Orth, Virchow's successor in the chair of pathology at Berlin University, holds that they tend to make out a case against the Koch theory. On the other hand, all the other authorities in Berlin take the opposite view and consider that Koch's position is impregnable. On his return to the capital Prof. Koch announced that the report confirmed him in his original position. He took the opportunity to restate his conclusions as follows: that the transmission of bovine tuberculosis to man cannot take place by means of food; that neither bovine flesh nor milk can transfer the disease; that is was possible for a butcher at the slaughter houses to become infected by injuring himself when handling tuberculous meat, but even then the infection remained local and caused no general disease. With regard to the report of the Royal Commission, he said, emphatically: "It does not contain a single fact to make me change my opinion, which is based on very careful experiments, not only made by myself and my assistants, but also by other medical men of the highest standing. It is for my opponents to prove that I am wrong. I have tried for years to find a case in which tuberculosis was transferred from animals to men. Three years ago the Prussian Minister for Public Instruction, at my request, instructed all physicians in charge of the large public hospitals to report all cases which came to their notice of bovine tuberculosis having been transmitted to man, and up to this day we have been waiting to hear of the first case. As long as the Royal Commission does not show me a case in which such infection is proved, I can not believe in its assertion. If it be true, as is stated by veterinary surgeons, that a half of 1 per cent. of all cows suffer from bovine tuberculosis, while the Prussian Royal Commission could not point to one case of infection from the drinking of the milk of such animals, it looks as if there were good grounds for Prof. Koch's protest against certain precautions now in legal force nearly everywhere. He holds that the millions wasted by the killing of the animals and for the sterilization and pasteurization of milk ought to be saved and turned to really practical use in combating the dread disease and obtaining mastery over it.

OBITUARY.

Dr. Edward W. Lambert, one of the oldest and most prominent physicians in New York, died from heart disease at his home, 126 East Thirty-ninth Street, on Sunday night, July 17, 1904, after an illness of about a week. Dr. Lambert celebrated his seventy-third birthday on Feb. 15 last, having been born in Boston, Mass., in 1831. At the age of twenty-three he was graduated from Yale University, and immediately began the study of medicine at the College of Physicians and Surgeons. After receiving his diploma he served as visiting physician in Bellevue Hospital, and began the practice of medicine for himself in 1857. In college and in the office of Dr. Willard Parker, where he was an assistant, Dr. Lambert was associated with Drs. Henry B. Sands and William H. Draper. At the time of his death he was attending physician at St. Luke's Hospital and the Nursery and Child's Hospital. Dr. Lambert became associated with Henry B. Hyde in 1859, who in that year founded the Equitable Life Assurance Society, and was made the society's first medical director. During the period of forty-five years since then he had remained chief of the Equitable's medical staff, although for the last six months he had acted, for the most part, as consulting medical director. Dr. Lambert had a country residence at New Canaan, Conn. He was a member of the University Club, the Century and Yale Clubs, the New England Society, and the New York Academy of Medicine. He is survived by four sons and four daughters, three of the daughters being married. Of the sons, Adrian, Samuel, and Alexander Lambert are physicians in this city, while the fourth is a manufacturer of Manchester, N. H.

SOCIETY PROCEEDINGS.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, held April 19, 1904.

The President, O. H. Schultz, M.D., in the Chair.

Polycythemia in Congenital Heart Disease.—Dr. Isra S. Wile read a short paper on the polycythemia of congenital heart disease. He briefly reviewed the theories which have been devised to explain the phenomena and came to the conclusion the one which assumes the inspissation of the blood as a cause of polycythemia could not be regarded as explaining all of the facts. His own view was that the polycythemia was an expression of a physiological hyperplasia of the oxygen carrying red cells of the blood to compensate for the imperfect aeration which takes place in the lungs in congenital heart disease. The same compensation is required for the lowered hemoglobin content of the individual corpuscles in the blood as is seen in these cases.

Dr. E. E. Smith, in the discussion, said that Dr. Vogel had referred to the fact that in the application of the method, a variable amount of the reagent added was used to react with other constituents than albumen. This was a variable factor and interfered with the accuracy of the test to a certain extent. Dr. Smith inquired whether Dr. Vogel had considered the advisability of running a control by separating by the heat method the albumin from a portion of the urine, filtering it off and running a control on the filtrate as a factor for correction. That would take but a few moments,—acidify the urine with acetic acid, heat and filter and run a control on the filtrate. It seemed to him that would afford a correction.

Dr. Vogel said he understood what Dr. Smith meant and it might possibly afford a factor for a particular urine.

Dr. Smith said that he wanted to call attention to the fact that Esbach's method so generally used in office examinations was quite unreliable owing to the fact that the tubes manufactured are made on a wrong principle at the present time. The original principle upon which the Esbach tubes were made was the fact that the albumen precipitates out by gravity a certain

distance in a certain time. The tubes should have the U mark at a certain uniform height. The manufacturers had made the mistake of supposing that the U mark should represent the capacity of the tube. Consequently instead of being at a fixed height the U marks in the tubes now used varied greatly in position, with the result that there was a variation of 50 per cent. more or less, in the results obtained in the different tubes. Dr. Smith thought the fact important and that perhaps those who had not considered it would like to have their attention called to it.

Dr. P. A. Levene said that for clinical purposes the Esbach method was quite satisfactory. The presence of a few milligrams more or less of proteid in the urine does not indicate any alteration in the conditions of the kidneys. It was of importance to have a general knowledge whether the urine contained small or large quantities of albumin, and a similar knowledge of the decrease or increase of the substance in disease. Such knowledge it was possible to obtain by Esbach's method. Dr. Levene did not believe that it would be possible to devise a reliable volumetric method for the estimation of proteids, for the reason that proteids combine with other substances very slowly.

Dr. George Mannheimer said that he had not often made quantitative estimates of albumin in urine, because they seemed to him not of great clinical value. The amount of albumin he considered diagnostic only in certain conditions of the kidney; *e.g.*, congestion due to heart disease, where it varied with the state of the circulation. In cases of chronic nephritis, the degree of albuminuria varied so much from day to day that it could not serve as a guide to the severity of the disease. Von Noorden brought out, years ago, the fact that the variations were so great as to be almost characteristic of chronic Bright's disease. In a few cases where it had seemed of interest to estimate how much albumin was passed in twenty-four hours, he had determined the total nitrogen by the Kjeldahl method, first with the albuminous urine, and then with a thoroughly disalbuminized specimen of the same twenty-four hours' collection. The difference between the two results indicated the amount of albumin. This procedure had been compared with the weighing method as a standard and the error had been found to be less than 1-100 of one per cent. Esbach's method in spite of its faults seemed a convenient clinical one to use for continuous estimation in a given case. If employed always under the same circumstances, the same mistake would always be made and it could thus be used for comparison. Dr. Mannheimer asked Dr. Vogel whether he had tested the method he described against any other reliable one.

Dr. Smith said he had not anticipated Dr. Levene's remarks on the Esbach method. In view of the fact that Dr. Levene inferred that the Esbach method was used by all, he thought it would be well to describe the method he used in his routine work. It was quite simple and had an advantage over the Esbach method in that it took less time to get final results. It was practically a simplified gravimetric method. He took a small quantity of urine, an amount that he estimated would contain about 20 milligrams of albumin. This he diluted with a saturated solution of common salt, coagulated with heat and acetic acid; let it stand on a water bath for a few moments until the coagulum was well formed, and filtered through a Gooch crucible, or through a small, weighted, folded filter. The precipitate was washed with hot water, alcohol, and ether. All this took but little time and for any one who did it in a routine way it was very simple. The Gooch or filter was dried in an oven for three hours at 110° F.—a much more than ample time to thoroughly dry the precipitate. It is then cooled and weighed, and in the case of the Gooch, ignited and reweighed. This gave a ready method for the estimation of albumin; in the laboratory it could be done in half a day; and the method was much more satisfactory than that of Esbach, and one that the speaker thought would be followed with advantage by those who had the equipment of a laboratory.

Dr. Vogel said that the control determinations were made by the method of Scherer, which consists in carefully acidulating with acetic acid and then coagulating the albumin by heating on the water bath for one-half hour. The speaker added a certain amount of salt solution before heating in order to ensure complete precipitation of the albumin. The fluid was then filtered through a dried, weighed filter; the precipitate washed with water, alcohol and ether, dried to constant weight, and the amount of albumin determined. That, he thought, was the method usually considered the most accurate. Incineration of the filter was not necessary if the amount of precipitate were not large and the washing was thoroughly done. The study had seemed advisable for the reason that this method of Wassiliew's has been reproduced in a number of different textbooks, always without any special comments, which indicate that it had been accepted. Dr. Vogel had thought it did not seem right to have the method go on, perpetuated indefinitely, without investigation, so he undertook it. The result had been rather unsatisfactory to the method.

As to Dr. Levene's remark that no titration method of determining the amount of albumin was likely to be successful, Dr. Vogel said in this investigation everything had pointed to that fact. It appeared that the union of the sulphosalicyclic acid with the proteid took place quite slowly and evidently incompletely, so that there was no definite means of knowing when complete union had taken place. Probably, also, the fact that albumin which originates from different sources may have different affinities for acids, entered into the question.

As to Dr. Smith's remarks, Dr. Vogel said that in carrying out the determinations a large number of parallel determinations with the Esbach tube had been made. He could only corroborate what Dr. Smith had said as to the unreliability of the Esbach method. The gravimetric method described was extremely accurate but, for the practitioner, entirely impracticable. He thought a method which could be applied to the purposes of daily routine use without such expenditure of time, and yet would afford fairly reasonable accuracy, was the desideratum. Some German authors used tables from which the amount of weighed albumin corresponding to given bulks of precipitate settling in the test tube after boiling, and roughly gauged by the eye, might be determined. This method was open to gross errors, but was said not to be more so than the Esbach. It was not necessary for clinical use to know the exact number of milligrams to the liter but to know whether the amount was increasing or diminishing from day to day.

Some Observations on Complement.—Dr. Edna Steinhardt read some observations on complement. The work had been carried out in the Research Laboratory of the Health Department, through the kind permission of Dr. W. H. Park, whom she wished to thank for his courtesy and for his many suggestions and criticisms. Her thanks were also due to Dr. Anna W. Williams for her suggestions during the course of the work.

The points under consideration were: (1) The effect on the complement of passing serum through a Berke-

feld filter. (2) The differentiation of bacteriolytic complements by means of a filter, by heat, and by preservation. It was found that the fresh serum of the horse was lytic to the stock typhoid culture, so this combination was used in the following experiments. When fresh lytic serum was passed through a small Berkefeld filter, the first 10 c.c. had lost its lytic action, the second 10 was partially active; the third more so, while the fourth 10 was unimpaired in its lytic strength. This gradual passage of the lytic property of the serum through a Berkefeld filter accords with the same fact noted by Graham-Smith, for the precipitins,[1] and by Park and Collins for the agglutinins.[2] There are, however, in lytic action, two factors to be considered, the immune body and the complement. The question is: Is the first filtrate lacking in one or both? Ehrlich and Morgenroth and Ainley Walker state that the immune body is present in the filtrate; while Pfeiffer, who filtered small quantities of serum, noted considerable reduction of the immune body. To test this point, portions of the first 10 c.c. passed through the filter were added to fresh lytic serum and the Neisser and Wechsberg phenomenon of deviation of the complement, due to excess of immune body, was produced. Therefore, though there may have been a diminution of immune body in the filtrate, still there was sufficient present to produce lysis, if there had not been a lack of complement. Ehrlich and Morgenroth state this retention of complement to be due to absorption to the filter. This was proven to be so by passing 10 c.c. of a lytic serum through a small Berkefeld filter. Five c.c. of this filtrate were then drawn through the filter in the reverse direction. The first filtrate was tested and found to be non-lytic; while that portion which had been passed back through the filter was lytic to a certain extent, though not to the same degree as the original serum. This difference in strength is easily explained by the fact that it would be impossible with such a small amount of fluid to wash the filter clear.

This same fact of absorption was shown by another method: namely, 10 c.c. of the lytic serum were drawn through a Berkefeld filter. The filtrate was removed, and proven to be inactive. Then 25 c.c. of .8 per cent. NaCl solution were drawn through this filter in the same direction. This washing was evaporated to dryness in a vacuum over sulphuric acid at room temperature, and the residue when dissolved was distinctly lytic. To control this, lytic unfiltered serum evaporated in the same manner was shown to still retain its lytic properties, while neither inactive evaporated serum, nor concentrated NaCl solution had any lytic effect when tested. It was also shown that if 25 to 30 c.c. of inactive serum were passed through a filter and then 10 c.c. of a lytic serum were drawn through, this last serum would still retain its lytic quality. In other words, the coating of the filter is purely mechanical, the filter having no selective action for the complement. The complement, however, usually exists in serum in so much smaller proportions than the immune body that in the first few cubic centimeters of a filtrate it is probably present, though in such minute quantities that it is impossible to detect it with our present technic.

Ehrlich and Morgenroth found that they were able to differentiate two hemolytic complements by filtering serum. This was corroborated by Neisser and Döring. Later Vedder repeated this for the bacteriolytic complements. There are three hypotheses that suggest themselves as possible explanations for this separation of complements by a filter: (1) The difference in size of the molecules of the different complements. (2) The difference in the adhesiveness of the molecules. (3) The difference quantitatively of the various complements.

As to the first, it seems rather improbable that a molecule should be large enough to block the pores of a Berkefeld filter, which are comparatively coarse. The second may be the explanation; but the next hypothesis seems the more probable one, as indicated by the results so far obtained.

In rabbits' serum the greatest lytic action occurs for the typhoid bacillus, less for the dysentery, and least for the colon; and when Vedder filtered rabbits' serum, he found absence of lysis for the colon, impaired for the dysentery, and unimpaired for the typhoid organisms. To take the agglutinins as an example, in a serum which contains twice the amount of agglutinins for Flexner "Baltimore" as it does for Penman (two dysentery organisms), when a few c.c. of this serum were filtered and this filtrate tested, it was found that the agglutinins were reduced proportionally; that is two-thirds of each had been retained in the filter. It would be possible by the testing of successive filtrates to find that point where no visible reaction could be obtained with Penman, but Flexner "Baltimore" would still in certain dilutions be agglutinated; thus apparently differentiating by a filter between the two agglutinins. The tests for small amounts of agglutinins are, however, much more delicate than those for complement. For this reason, with the present methods a trace of complement could not be detected and would be called absent. Therefore it seems probable that the differentiation by the filter of bacteriolytic complements is a quantitative rather than a qualitative one.

Tests were also made upon the differentiation of bacteriolytic complement by heat, and here the typhoid complement was found to be more resistant than the colon or dysentery complement, but the serum originally was more lytic toward typhoid than towards either of the other two. Also, the complement for the typhoid bacillus was present longer in preserved serum than was that for the dysentery organism.

It may be that the differentiation of bacteriolytic complements by heating, and by permanency, as well as by filtration, is explainable by the same theory of quantitative differences in their amounts originally present in the serum. However, as yet this is only an hypothesis suggested by the similarity of results obtained in all three experiments, and further work will have to be done on the points, before this theory can be proven or disproven.

In conclusion, the results obtained were summed up as follows: (1) The gradual passage of bacteriolytic complement through the Berkefeld filter. (2) The retention of complement of the first portions of the filtrate by the filter being due to absorption. (3) The probable explanation of the differentiation of bacteriolytic complements by filtration is their quantitative differences in the original serum. (4) The similarity of results obtained by the effects of heat and by the effect of time on certain bacteriolytic complements, suggests their explanation on the same basis.

Dr. P. A. Levene, in the discussion, remarked that the observations of Ehrlich that certain complements did not pass Berkefeld filters might be explained by the supposition that they were in colloidal solution. The more soluble complements would pass through the filter more readily. It was not of so much importance to know whether the Berkefeld filter is absolutely or partly impermeable for a complement, as it is to be able to separate the substances by means of filtration. Ehrlich might have achieved this owing to his great experience

1 Journal of Hygiene, July, 1903.
2 Proceedings of the New York Pathological Society, Jan., 1904.

in handling these substances, and to his knowledge of their behavior under different conditions.

Dr. Steinhardt replied that there was no doubt at all of the separation of complements by means of a filter, as shown by Ehrlich, and repeated by other workers. The question had been only of the reason for this separation. The supposition of the colloidal nature of some of the complements causing their retention in the filter might be correct. It was rather difficult, however, on that basis, to understand the passage in the first few cubic centimeters of serum, of the complement for the typhoid bacillus through a filter previously coated with inactive serum, which complement would be completely retained by using an uncoated filter. Also, the proportionate reduction in filtered agglutinins and the similar results obtained for bacteriolytic complements suggested the probable explanation as being a difference in the several complements of quantity rather than quality.

On the Presence of Mallory's Cyclaster Scarlarinalis in the Skin of Scarlet Fever Patients.—This was the subject of Dr. Cyrus W. Field. He said that these bodies were described by Dr. Mallory before the Society of Medical Research in Boston, on the fifteenth of December, his paper being published in the January number of the *Journal of Medical Research,* 1904. He had found the bodies first in the skin of a boy who had died on the third day of the rash. There were three specimens examined, one each from the thorax, abdomen, and thigh. One of these pieces showed the bodies present in the epithelial cells, between the lymph cells, and in the lymph space of the corium. In another piece there were a few and in a third none at all. Dr. Mallory had examined this specimen as he wished to compare forms of degeneration in scarlatina with those found in variola, and had found bodies he had noticed before. He had had three other cases in which the same bodies were found. These scarlatinal bodies stain only by the eosin methylene blue stain and can not be demonstrated by the hemotoxylin or Borrell stain. Dr. Mallory had tried a number of other stains, as had Dr. Field. Alcohol hardened sections could be used, but alcohol is not a good fixative, Zenker's giving by far the best results. Dr. Mallory had stated that the bodies first appeared in the epithelial cells of the deeper layers, as small rosette like bodies connected by more delicate lighter blue staining material with a central point. In a later stage they break up and then enlarge in the cell. These large bodies were homogeneous, staining with methylene blue, and as they increased they became reticular. They were both intra- and extracellular and the latter showed what appeared to be ameboid motion. The determination of the exact pathological significance of these bodies is a very difficult matter and it cannot be proved on purely morphological grounds. In sections of corneas treated with diphtheria toxin, Dr. Ewing has shown that we can get keratinization which simulates the ameboid forms. It is supposed that they enter the cells and there become larger, thickening, and giving out a smaller reticular structure; then they enlarge gradually, become more dense, homogeneous, shrink, and finally form rosettes again; how many times they pass through the cycle Dr. Mallory was not prepared to say. He had found them in four cases in the skin, in the epithelial lymph sinuses of the tongue in one. Dr. Field had examined skin from the groin of five scarlet fever patients dead from the disease, two patients dying on the third day of the rash, one on the second day, two on the fourth day. In all five cases he had found these bodies. Dr. Mallory had examined them and had agreed that they were similar to those he found. Dr. Field had also examined the skin of four patients living at the time the skin was taken; in one case on the first day, in two cases on the fifth day, and in one on the sixth day of disease. In none had he been able to demonstrate the presence of these bodies. The skin had been taken from the thorax and not from the thigh. He had been able to find reticular bodies in the cells, a few outside of cells, and a few he was not sure of, and he was not sure at all what they were in the lymph sinuses. He had been unable to find any of Dr. Mallory's rosettes. In Dr. Field's opinion these bodies were much more definite and delicate in structure than any degeneration he had seen. They stained in a manner similar to the malarial parasite, but not so intensely. They do not take up methylene blue so intensely. What their origin is, or how they pass into the skin, Dr. Field did not know, except that from the appearance of the skin they seemed to have entered by way of the lymphatics. He thought the significance of the bodies might be determined from the morphological status in time, but he thought the problem would require a good deal of control work on sections of skin from a variety of conditions. He did not accept them as protozoa or degeneration, and at present was a complete agnostic on the subject.

Dr. I. Levin, in the discussion, said that ten years ago he did a great deal of work on the protozoa of cancer. When he turned to this study two facts struck him, (1) that the so-called protozoa of cancer resembled to a great extent the formations found in smallpox or scarlet fever, so that without the inscription he could hardly distinguish one from the other; (2) he found in his study of the protozoa of cancer, that it was easiest to find these pictures in skin cancer—ulcus rodens. This might be caused either by the fact that the epithelium of the epidermis undergoes sooner different processes of degeneration or that the protozoa penetrate the skin more easily than the other tissues. It rather spoke against the parasitic theory that the ulcus rodens is comparatively a benign cancer. In this question as in a number of others in pathology, the morphologist was powerless to solve the problem unaided. Until such time as experimental pathology could find some way to get nearer to the physiology of the parasite, we would spend a great deal of time and energy and say at the end: "I do not know whether it is a degeneration or a protozoon."

Dr. Field said that he thought Dr. Levin had put it too strongly in saying the student could not decide the question. Dr. Field thought that with control work the question could be decided. The malarial parasite had been found to be an etiological factor in malaria. Had it been impossible to discover it in the blood it would have been found to be very characteristic in the stained sections. He thought any one who had looked at Dr. Homer Wright's specimens from the Delhi boil, in which he demonstrated the parasite in that disease, would agree that these questions could be decided in that way. He thought the question under discussion could be decided in the same way if studied long enough. The bodies were striking and particularly well differentiated. Dr. Field thought, however, that it would require a great deal of work on numerous skin lesions or internal organs of scarlet fever patients before the nature of the lesion could be decided, but he did not despair of in time being able to help in the matter.

A Case Simulating Hodgkin's Disease.—Dr. Harlow Brooks showed specimens from a case simulating Hodgkin's disease. The patient was a boy about twelve years of age. He had been at the Montefiore Home for three years. The history of the case dated back to April, 1901. The onset of the disease had been sudden with vomiting, loss of consciousness and pains in the abdomen. The patient was prepared for an operation for appendicitis;

but on palpation over the abdomen the tumor formation was found and it was decided not to operate. In two weeks the boy improved and was taken home. Later, the abdomen began to grow and he stooped forward, complaining of pain on the left side in the region of the bladder. Afterward some diminution in the size of the abdomen took place but the boy still walked in a peculiar position, the thigh on the left side held rigid and the body stooped over to relax the muscles of that thigh. Subjectively he complained of nothing. Physical examination showed a poorly developed, poorly nourished, dark complexioned boy, no skeletal deformities, no skin lesions. Thoracic organs negative; veins anemic. The glands of the groin were palpable but at first without perceptible enlargement. He fattened up considerably after four years in the hospital but the abdominal circumference increased. Nothing of any importance developed in the thoracic condition. An exploratory laparotomy was performed, and, commencing at the median line in the abdomen, a glandular growth was found. A nodule was removed for microscopical examination and a diagnosis of probable peritoneal endothelioma was made. Frequent blood examinations were made but no leucocytosis was found up to shortly before death when complicating lesions caused the development of leucocytosis. Differential leucocyte counts had shown the relative percentages to be approximately normal. The treatment of the case was unimportant and without effect on the course of the disease. Dr. Brooks showed the organs from the case. The heart was negative. The lungs showed intralobular pleurisy; their tissue was salmon colored, very firm, and showed microscopical changes like those of the ordinary cardiac lung. Dr. Brooks had thought at the time of autopsy that an infiltration of lymphocytes into the lung was present, but microscopically this was not substantiated. A moderate increase in fibrous connective tissue was found; otherwise the lung was like that in ordinary cardiac cases. The glands of the neck were enlarged to a considerable degree. The precardial lymph-nodes were moderately enlarged; those at the bifurcation were markedly so. They were very firm and light pink in color. Dr. Brooks had described the liver in his postmortem examination as showing lymphoid infiltration, but this was disproven microscopically. The spleen was enormously enlarged. There were whitish nodes present in it which Dr. Brooks took to be hypertrophic Malpighian bodies. Microscopically these were found to be made up of dense masses of fibroblasts and connective tissue fibrils, and in places amyloid degeneration had taken place. On opening the stomach Dr. Brooks had found whitish patches which he took to be infiltration with lymphocytes, but which proved to be areas of fibrosis. Microscopically the kidneys were also found free from leucocytic infiltration.

The main abdominal tumor was found to be made up of the greatly hypertrophied retroperitoneal lymph-nodes which although they still preserved their general contour had grown so in size that some of them measured as much at 10 cm. in diameter. Their tissue was found to be very firm and no areas of necrosis could be made out, though in certain places the tissue was slightly yellowish. The capsules of the glands seemed to be intact throughout and although they were firmly attached to the surrounding structures and to the periosteum of the vertebræ, infiltration outside the nodes could be made out nowhere. Microscopically the structure of these nodes varied greatly though all were characterized by replacement of the normal lymphoid cells by masses of proliferating fibroblasts and connective tissue tendrils. Some of the nodes showed between this connective tissue network very numerous giant cells, having, however, no definite arrangement; nothing like tubercle formation was to be made out in any of the sections. A few of the lesser enlarged nodes showed apparently a simple hyperplasia of the lymphoid cells, such as one sees in the nodes of typical cases of Hodgkin's disease. In the left iliac fossa was a great mass of enlarged glands measuring 13 by 8 cm. The microscopical structure was found to vary in the degree of fibrosis as did the other nodes previously described. A few of the nodes here on gross examination showed a curious yellow pigment deposit, like a sprinkling of the surface with sulphur. Microscopically this pigment was found to be deposited in the cytoplasm of the lymphoid and connective tissue cells. Although these glands practically filled the iliac fossa on this side and by their pressure and that of the corresponding enlarged inguinal lymph-nodes caused the flexed position of the left thigh, in no place had the growth invaded outside tissues, not even the periosteum of the iliac bone to which the mass was firmly attached.

Dr. Brooks thought the diagnosis of the case lay between sarcoma and Hodgkin's disease, in which the hyperplastic lymph-cells had been replaced by fibrous connective tissue. He had never heard of nor seen a case in which replacement was so complete as in this instance, or one in which the picture presented by different glands varied so markedly. There was no typical fibrillar arrangement leading to the diagnosis of syphilis and this diagnosis would have suggested some disease of the bone—some skin manifestations, some syphilitic symptoms—none of which was present in this case. With syphilitic glands so large as these necrosis would probably have been found somewhere in the nodes. Tuberculosis had, of course, been considered, and Dr. Brooks thought excluded, because in this enormous mass of tissue one would expect to find something fairly characteristic of it, were it tuberculous. Sarcoma might be diagnosed, in which case it must be classed as a fibrosarcoma; but it is contrary to our knowledge of this growth to have it limited to the lymphoid tissues, as in this case. If sarcoma, we would have expected the tumor cells to have infiltrated outside of the Malpighian bodies, in the spleen, for instance. We would also have expected the growth to burst out through the capsule of the glands and to have invaded the surrounding structures. Dr. Brooks thought it a case of Hodgkin's disease in which there was replacement of the hyperplastic lymph tissue by the connective tissue hyperplasia which is found so commonly in chronic inflammatory processes.

Dr. Ewing said that he had examined the sections from Dr. Brooks' cases, and believed that both the histology and the gross appearance left no room to doubt that the case was one of Hodgkin's disease. Compared with others the tissue in this case contained many more giant cells than is usual, and these cells gave the section somewhat of a sarcomatous appearance. This histology had been regarded for many years in Vienna as pathognomonic of Hodgkin's disease, and although it seemed to be less frequent in New York, it had recently been described anew in a series of cases by a Baltimore writer.

In some cases of *constitutio lymphatica* he had seen a good many giant cells in the hyperplastic lymph nodes, and would like to know if in this case there were any of the signs of the lymphatic constitution, such as rickets or persistent thymus. The absence of necrosis, while characterictic of this type of Hodgkin's disease, did not, Dr. Ewing believed, rule out a tuberculous origin, which could only be attempted by inoculations of large amounts of the material. On the histology alone he did not think it possible to exclude tuberculosis.

Dr. Brill said that the doubt expressed by Dr. Brooks

as to the pathological nature of this case was but another indication of our lack of knowledge of the pathology of Hodgkin's disease. While the disease represents a definite clinical entity, its pathology presents a number of various and not allied or identical conditions. Clinically, the disease presents anemia without marked qualitative changes in the red and white cells of the blood, enlargement of the lymph nodes, and in almost all cases, more or less increase in the size of the spleen, accompanying progressive weakness, and finally, almost invariably a fatal issue in two or three years or less. When the disease is considered histologically and pathologically, it represents this clinical picture arising from a lymphoid hyperplasia, not induced by tuberculosis, syphilis, rachitis, or sarcoma. It is here where our knowledge is at fault, for cases clinically like Hodgkin's disease occur, which on pathological examination may prove to be any one of the conditions just mentioned; namely, tuberculosis, sarcoma, or syphilis.

However, because a change in some of the lymph nodes in a case of Hodgkin's disease may be due to tuberculosis of these nodes, we are not justified in assuming that that case is not one of Hodgkin's disease, for there is no reason why a coincidental infection with tuberculosis may not exist together with the original infection, if we may call Hodgkin's disease an infection, as it would seem to be from many of its pathological aspects.

The case presented by Dr. Brooks was extremely interesting from both the clinical and the pathological points of view and Dr. Brill asked whether Dr. Brooks could say in which groups of lymp-nodes enlargement was first noticed, whether the cervical, mediastinal, retroperitoneal, mesenteric or inguinal.

Dr. Brooks replied that he had first observed the growths in question in the retroperitoneal region.

Dr. Brill said that this was against the rule in Hodgkin's disease, where the lymph-nodes of the anterior cervical or mediastinal regions were commonly first involved, considerably before the retroperitoneal or inguinal nodes. From a clinical aspect there was no reason to call this case of Dr. Brooks' anything else than one of Hodgkin's disease.

Dr. Brooks said he felt somewhat comforted at the remarks made. He said the more he studied the glands the more each one seemed to show a different picture. He could not get rid of the idea that the case was one of Hodgkin's disease, but it differed from all cases as he had seen it, and the changes in the glands were not as usually found in that disease, so far as he had been able to examine them, having studied about thirty instances. They also differed from those of any case he had read of. In regard to status lymphaticus, the linguinal adenoids were noted as moderately enlarged in the protocol, but the tonsils were not hypertrophic, and the thymus was absent. In the detailed autopsy, only the outlines of which had been read, he did not find anything which led him to think it was status lymphaticus. The thickened areas in the walls of the stomach and gut which he had taken to be lymphoid infiltration, proved to be fibroid thickening. On the dorsum of the tongue he had found a small excavated, even-floored ulcer, which looked like a trophic ulcer. The child had never complained of this and it was only discovered post mortem. At one side of this ulcer was a small mass of connective tissue which might have been considered a tubercle if any other tubercles had been seen in other portions.

HARVARD MEDICAL SOCIETY OF NEW YORK CITY.

Regular Monthly Meeting, held March 26, 1904.

The President, Augustus H. Knight, M.D., in the Chair.

Sepsis After Operation for Adenoids.—Dr. Charles Schramm reported in detail a case in which septic fever followed operation for the removal of adenoids after an interval of several days. The patient, a child of six years, had been in very good health, having up to the present escaped diphtheria and the other ordinary infectious diseases of childhood and even the minor ailments of the earlier years. She had not been under medical observation for four or five months, when her mother brought her to the doctor for obstructive respiratory symptoms which had gradually developed during the five or six weeks immediately preceding. The child had become a mouth-breather during this interval and had also developed slight deafness, besides suffering from a constant nasal discharge. The vault of the pharynx was found filled with a succulent mass of tissue almost entirely obstructing the posterior nares. The tonsils were not enlarged, nor were the cervical lymph-nodes affected. A persistent dermatitis of the upper lip was sufficient evidence of the irritant character of the nasal discharge which had existed for several weeks. There was slight cough, but only scanty expectoration. The appetite was not impaired and there was some dyspnea on exertion. This probably made the child disinclined to exert herself at play or otherwise. The eyes were watery. The chest expansion was good and the lungs gave no evidence of inflammatory irritation. The heart action was good and its sounds normal, the urine negative. The patient was removed to a private hospital for operation in the morning and was operated on the afternoon of the same day, after due preparation as to diet. The day after the operation she was removed to her home. The anesthetic used was chloroform, and every precaution to secure asepsis to instruments and surroundings was taken. The growth was easily removed in three pieces, the first as large as a hazelnut the others about one-fourth the size. The bleeding was not excessive; in fact, rather less than usual. The child's head was frequently turned over the edge of the table to give free exit to blood and secretion. Besides, she was not deeply anesthetized and voluntarily hawked and spit out some of the blood and mucus. The tissue removed was mushy, the child was seen at her home on the afternoon of the next day. She was up and about, feeling as well and active as usual. The symptoms of respiratory and tubal obstruction were entirely relieved. The child was seen again four days later in the afternoon. She had been listless all day and complained of chilliness and headache. She preferred to lie in bed. She had no appetite, though to careful examination the throat and lungs were negative. The tongue was coated, the eyes slightly yellow, the abdomen distended but not tender, the temperature was 102.5° F., the respiration 30, the pulse 124. The next morning she seemed much improved, the temperature had fallen to 99° F. and the pulse to 100, the throat was negative. In fact, the whole trouble was considered intestinal, yielding to divided doses of calomel. In the evening, however, she was much worse, with a temperature of 104° F., pulse 140, respiration 38. She complained of pain in the left ear.

Progress of the Infectious Process.—On the next day she had a mild conjunctivitis with moderate purulent secretion. The pain in the ear having increased and hearing being almost nil, the membrana tympani was incised. A few drops of bloody pus escaped. The discharge never was abundant and soon became serous. Two days later the left membrane had to be incised with similar results. Throughout the disease there was

nothing abnormal to be seen in the throat. Three days after the onset the patient developed a persistent hacking cough which in two days became loose when coarse moist rales were to be heard all over both lungs, especially at the bases. No consolidation was demonstrable at any time. There was profuse perspiration at night. The nose began to discharge on the fifth day, the secretion being light-colored. The abdomen continued distended and the bowels sluggish. On the seventh day after their inception the symptoms, subjective and physical, began to subside. Normal sleep returned and with it the appetite. The congestion of the conjunctiva and the secretion from them disappeared. The nasal discharge ceased and hearing gradually returned. The cough continued for two weeks longer. The temperature, pulse and respiration were normal on the ninth day.

Adenoid Growths and Tendencies to Infection.—The condition previous to operation was apparently one of acute adenoiditis, a process of rapid proliferation of the lymphatic tissue, which in part constitutes the pharyngeal tonsil. This could have resulted apparently only from an acute infection. In this connection the opinion of W. N. Nikitin, writing in the *St. Petersburg Wochenschrift,* is interesting. The pharyngeal tonsil, instead of being possessed of phagocytic or protective powers, is especially liable to infection to a greater degree than other parts of the mucous membrane. The infective influence may extend to the lower respiratory organs. Not only is the enlarged tonsil a culture field, but, according to Dr. Wex, in the *Archives of Otology,* there may be a possible secretion of a toxic substance by the adenoid growth itself. If this case was one of sepsis resulting from infection of a denuded surface, an interval of three days for its development, *i.e.,* the period of incubation, would not be inconsistent with the diagnosis. The alternative of a grip infection, the disease being prevalent at the time, is rather invalidated by the course of the temperature which is characteristic of the former. However, acute otitis media might cause similar temperature changes, even if dependent on grip infection, hence there is room for doubt of this diagnosis. Two consulting physicians who examined the child's chest could find no evidence of pneumonia, nor was the temperature-pulse ratio indicative of it. It is remarkable that the medical literature of the past few years contains no similar case. The only allusion to a systemic infection following operation for the removal of adenoids appeared in a quotation from the *Journal of Laryngology* for October, 1901, where Wyatt Wingrave described a rash after adenoidectomy, which appeared on the second or third day. It was papular with an areola or erythematous in character; attacks the neck, chest and abdomen. It lasted two or three days. There was no desquamation and only slight constitutional disturbance.

Molecular Osmotic Tension of Fluids in the Body.—This, the regular scientific paper of the evening, was read by Dr. Edward K. Dunham. He explained the significance of differences in molecular tension and their methods of measurement. Direct observation of osmotic pressure is possible, but would require very delicate apparatus. There are two similar methods of measuring osmotic pressure: one is by finding the lowering of the freezing point of a solution, the other by observing the rise of the boiling point when substances are in solution in liquid that are submitted to either of these physical processes. It has been found that when one gram molecule is dissolved in a liter of water, the freezing point of the solution is lowered by 1.85 degrees on a centigrade thermometer. It is not difficult to obtain an instrument that will measure such slight and delicate variations of temperature very exactly. Dr. Dunham exhibited one which was marked in hundredths of a degree and which could be read to even smaller divisions than this, if necessary. Such a thermometer is made with a zero that changes from day to day according to temperature, but the zero point of which may be regulated by an actual observation in freezing pure water which gives the zero point for each daily set of observation.

Latent Heat.—A rather pretty demonstration of the existence of latent heat is made when water is frozen for these experiments in order to determine the freezing point of a solution. At first when the liquid to be observed is plunged into the freezing mixture the thermometer falls below the zero point. Then, as the water freezes, its latent heat is given out and the mercury rises rapidly to a point where it stays until all the liquid becomes ice, or until whatever ice has been in the liquid has entirely melted. This point represents the freezing point of the solution in question. The conductivity of liquids bears a definite relation to the molecular concentration of substances in solution, but there are certain exceptions that must be noted: For instance, if common salt be dissolved in water, a certain number of the atoms of hydrogen and chlorine are set free as ions, that is, atoms bearing a definite charge of electricity and the sodium and chlorine do not exist as free sodium and free chlorine which must be in a molecular condition but are in the ionic state. As a consequence of the presence of these ions the conductivity of the liquid is greatly increased. The measure of the electrical conductivity then becomes the measure of the electrical dissociation and is proportionate to the number of ions present.

Application to Formation of Lymph.—Certain of these principles can be applied to the investigation of the formation of lymph. Lymph formation is due to a number of factors. The most important are capillary pressure, tissue conditions, the permeability of the capillary wall, the osmotic pressure of the plasma, the osmotic pressure of the lymph, the osmotic pressure within the cells, and, finally, the permeability of cells. There are three processes in all transudation through animal membranes. The first consists of the mechanical squeezing through the membrane of fluid; the second is the passing of water through an animal membrane by osmosis; the third is the diffusion of substances in solution through a capillary wall. The albumin in a transudate finds its way through by a process of filtration. The study of transudates by cryoscopy gives a new set of data for the clinical recognition and differentiation of these more or less inflammatory fluids and some hint as to diagnosis and prognosis as a consequence. Ordinary blood depresses the freezing point by about .56 of a degree. Defibrinated blood is practically the same. Transudates vary between .52 and .64 in their effect upon the lowering of the freezing point. When transudates are studied with reference to these figures they are found usually to correspond to the averages given. But unexpected variations are found.

Anomalous Case.—In a patient seen at Bellevue, about a year ago, a special condition of the pleuritic fluid effused after an attack of pneumonia was found to exist. The patient was a scene shifter who had for a number of months been traveling through the country with a troupe in the performance of his regular duties. These usually consisted of a severe amount of active labor, requiring intense effort for a few minutes, after which the patient was likely to sit in a draft for a considerable period. He suffered from a pain in his chest for several months and then came down with a chill. Frank lobar pneumonia developed, but with some

pleurisy and effusion. The fluid removed depressed the freezing point by 1.40 degrees. This was the average of a large number of observations. Besides the electrical conductivity of the solution was lower than usual though the specific gravity was about that which obtains in pleural exudates. The pleural fluid was treated by ether, acetic ether and chloroform, but no special extractives were obtained. There was a slight trace of lactic acid in the fluid. The patient's blood was obtained and presented no special depression of the normal freezing point. This case seems to illustrate what may prove a very practical application of cryoscopic methods to clinical medicine. They will refer rather to prognosis than to diagnosis. It is evident that such a fluid could not be reabsorbed, since its molecular concentration is higher than that of the blood. The change, if any, would rather be in the opposite direction, since the influence of osmosis would make for this. It seems probable, however, that no interchange has taken place for a considerable period nor would it. The pain in the side, prolonged over many months, was a protracted attack of pleurisy which had brought on great thickening of the pleura. This was no longer a permeable membrane and hence no water passed from the blood into the pleural sac, after the exudate had once been formed. The excessive molecules present were not salts, hence it seems not unlikely that they were cleavage products of the large proteid molecules which had split into simpler molecules during their stay in the pleural cavity. Horse serum, subjected to the same conditions as that of the pleuritic fluid, by enclosure in a closed tube in an incubator kept at human temperature underwent no change. Bacteria introduced into the serum did not produce any change either. It seemed not improbable that the change noted was due to ferments from the tissues, especially such enzymes as occur on leucocytes. When some pleural fluid was obtained containing a large proportion of pus and leucocytes and some of this fluid was, under aseptic precautions, sealed in a tube, a change corresponding to the molecular concentration of the pleuritic fluid in the patient first mentioned was obtained. There was no apparent putrefaction, however, for the liquid had not changed in electrical conductivity. All putrefactive changes would give rise to ammonia, and the ammonia salts would lead to dissociation with the presence of free ions and consequent increase of electrical conductivity.

Chances of Absorption.—Where such high molecular concentration is found in a fluid there can be no hope of its reabsorption, and measures for its removal should be taken unless, indeed, by the injection of artificial serum the molecular concentration could be made more nearly similar to that of the blood, with consequent chance of natural absorption. This might produce an osmotic current toward the blood with relief of the condition.

Ionization.—Dr. Reynold Wilcox, in discussing Dr. Dunham's paper, said that these studies of molecular concentration and electrical conductivity with the relation to the presence of free ions in solution may open up a new chapter in the study of applied therapeutics, especially as regards the rational employment of drugs. There has been for some time a growing hope that the ionic theory may serve as a new basis for pharmacology. As is well understood, little is known about the real action of drugs in the human body and the fact that even ordinary sulphuric acid may exist in solution in two different forms gives some idea of the complexity of the problems presented. Alcohol is now recognized to be antidote of carbolic acid, but this is not so much because it dilutes carbolic acid, nor even because it is an alcohol and thus a congener of phenol or carbolic acid, but apparently because it prevents the ionization of carbolic acid in the presence of human tissues. Olive oil seems to act in something of the same way and it has been recognized that solutions of phenol in olive oil do not dissociate and hence are not likely to be effective as antiseptics. It has been known for some time that the degree of ionization of a substance in solution varies with the dilution and the temperature. It has been hard to find the exact influence of such factors. The use of electrical conductivity as a measure of ionization, however, may prove a very practical method of determining factors that were nitherto only to be found by delicate methods. Cryoscopy has proved a disappointment in furnishing any special information with regard to the urine, but it seems not unlikely that it will prove of decided advantage in the more complex problems of physiological chemistry in normal conditions within the body.

Cryoscopy of Exudations.—Dr. John H. Huddleston said that Dr. Dunham's novel deductions with regard to exudates and transudates after examination by cryoscopic methods seem to furnish a new field for the application of cryoscopy. He has been rather disappointed in the use of cryoscopy for urinary investigation, but these suggestions open up a new and important outlook and seem to add a definite prognostic feature to the diagnostic promise, while it is also shown that there are even some suggestions as to treatment that may be derived from cryoscopic investigation of pleuritic and other exudates. These will undoubtedly prove welcome additions to the armamentarium of the clinician and especially of the laboratory specialist.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, held Thursday evening, March 17, 1904.

The President, Dr. Andrew H. Smith, in the Chair.

THE scientific business of the evening consisted of a symposium on headache and its relation to eye-strain. These papers will all appear in full in the MEDICAL NEWS.

Mental Disturbances and Eye-strain.—Dr. Charles L. Dana said that the eye is the only organ of special sense that is usually supposed to cause by reflex action various disturbances of the nervous system. No one has ever heard of ear strain or tongue strain. Eye-strain may be divided into two classes: subcortical eye-strain, that is reflex effects produced because of failure of the accommodative nervous mechanism to act properly, and cortical eye-strain due to the conscious effort to overcome ocular defects of various kinds. It is this latter that is supposed to be the basis of most of the functional nervous disturbances. It is well to realize that this is really a brain strain instead of an eye-strain. In Dr. Dana's opinion no true mental disease is ever due to reflex from the eye or is ever cured by correction of optical defects.

Exhaustion Psychoses.—Dr. Dana has seen certain cases of psychic depression associated with eye-strain in two classes of people. In the first the patient is usually a young adult who has been studying very hard. As the result of improper refraction and the conscious effort to overcome it after a time the student becomes unable to read or to study and a state of mental depression supervenes. A very curious phenomenon in these cases is that after a time the patient also does not care for outdoor sport, though he may previously have been much interested in it. Rest alone fails to cure the condition. After refractive errors are corrected, however, the patient's improvement is marked. The other class of patients is usually represented by men in their for-

ties suffering from the beginning presbyopia of advancing years. In these cases as the result of reflexes from the eyes mental depression to the extent almost of melancholia, with great irritability is known not infrequently to develop. The symptoms are relieved almost at once by the wearing of proper glasses and no other form of treatment is of avail. Not infrequently there is no symptom that points very distinctly to the eyes in these cases, and unless the physician is on the lookout for them the true cause of the mental depression may escape his notice.

Minor Psychoses and Eye-strain.—While it is often claimed that minor psychic disturbances are due to reflexes from the eye, Dr. Dana has not found this to be the case in practice. When the patient has a good mind to begin with, this is not overthrown by defects of vision. The only serious effects are produced on the minds of those who are already suffering from mental disturbances of low grade, due to heredity, or other causes. As a matter of fact, the only real mental affection connected with eye-strain, in Dr. Dana's opinion, is the symptom-complex with grandiose ideas on the part of ophthalmologists, who think that spectacles are so important and who are able to trace all the failures of genius and their ailments to the absence of spectacles.

Headache and Eye-strain.—Dr. C. W. Cutler discussed the relation of headache, migraine and other sensory disturbances to eye-strain. He does not consider that migraine should be considered merely as a sick headache, nor has he found that true forms of migraine are ever cured by the correction of refractive errors. Migraine occurs in unstable nervous organisms, that are readily influenced by peripheral irritation of any kind. Heredity is a prominent feature and the periodicity shows the serious affection of the nervous system which underlies it. Where migraine is an equivalent of epilepsy eye treatment is of no avail. On the other hand, where migraine is due to peripheral irritation alone, then the correction of refractive errors as one of the sources of peripheral irritation may bring about relief. While heredity is a prominent element in migraine, it must not be forgotten that the heredity of eye defects is very common. Another important point is that not infrequently the general health needs improvement after refractive errors have been corrected, or the patient's symptoms will not be relieved.

Motor Disturbances and Eye Disease.—Dr. B. Sachs discussed the relation of epilepsy, chorea and the convulsive tics to eye affections. He said that the dependence of the motor neuroses so-called on eye-strain had been greatly exaggerated. As the true nature of these neuroses comes to be better understood, fewer cures are reported. With regard to epilepsy, it is only in American literature as a rule that supposed cures of this serious nervous disease are reported by the oculist. Neurologists have not reported such cases, and in the recent large monographs published in Europe, on epilepsy, very little attention is paid the question of eye-strain. The investigating committee of the Neurological Society of New York some years ago investigated the question of the cures of epilepsy by the correction of eye defects and after carefully following fourteen cases, found that not one of them had been improved and that the evidence in other reported cases was untrustworthy. The reports of such cures can only be looked upon as morbid literary products.

Craig Colony Experience.—Recently a committee investigated the condition of the eyes of epileptics at Craig Colony. A much larger proportion than is usual among people of their years were found to be suffering from various eye defects. The refractive errors were therefore carefully corrected and disturbances of muscle balance adjusted. After a full year's experience of the patients under the altered circumstances the report of the condition of these patients, 68 in all, shows that one of them has been improved somewhat, but that all of the others have remained in the same condition as they were before. Almost any procedure with therapeutic suggestiveness in it would have given better results than tris, though much was hoped for it and much more written about the causative effect of such eye disturbances in the production of epilepsy.

Chorea and Eye-strain.—Dr. Sachs has never seen a case of true chorea benefited by a correction of refractive errors. Habit chorea, which often resembles true chorea, may begin in efforts to make up for refractive errors and this may be completely cured by the adjustment of proper spectacles. While habit chorea is usually of the face, it may affect other parts of the body and especially the shoulders and arms, and even these manifestations may be cured by the wearing of spectacles. In epilepsy it is as common to see patients wearing glasses as to find on them the evidence of a bromide rash. When other procedures than the fitting of glasses is attempted, even to operations, the ophthalmologist's work seems unjustified. Dr. Sachs has seen a teacher who suffered from occasional nocturnal epilepsy treated by tenotomy and thus made to suffer from double vision which was very annoying to him, though his nocturnal epilepsy had proved a source of very little inconvenience, beyond apprehension.

Hysteria and the Eye.—Dr. Ward A. Holden discussed the relation of the eye to hysteria, neurasthenia and the traumatic neuroses. The most constant symptom of hysteria is the concentric contraction of the visual fields. There are, however, various anomalous symptoms, occasionally double vision to a certain degree; or, on the other hand, hemianopsia are not unusual. In one case the candle flame was seen single in all directions up to fifteen feet, but double after that. After the concentric contraction of the visual fields the spiral field is the most usual; that is, the patient when examined shows at first a contraction of the fields and this grows smaller and smaller as the examination continues. Anomalous fields sometimes occur. The anesthesia of the retina corresponds in certain ways to other anesthetic stigmata of hysteria and traumatic neuroses and there may be hyperesthesia with supersensitiveness to light or with the occurrence of peculiar figures in light before the eye that also correspond to other hysterical conditions.

Functional Neuroses and the Eye.—Dr. G. E. de Schweinitz, of Philadelphia, opened the discussion by saying that eye-strain is not necessarily brain-strain in a person of lowered mental equilibration, but brain-strain may be due to eye-strain, even where there is no lowered constitutional condition. Practically every ophthalmologist must have seen, and not infrequently, the condition of depression, sometimes going on to melancholia, which develops in adults past middle life as presbyopia becomes a marked feature of their vision. In early life the backwardness of children must often be attributed to visual defects that need correction. Dr. de Schweinitz considers it very important to remember that it is not the marked errors of refraction which cause mental and nervous phenomena, but, on the contrary, trifling errors are more serious in their effects. The constant effort to overcome these wears out the nervous mechanism. Where the error is large, after a time nature refuses even to try to compensate for it, and so nervous and mental disturbances do not occur.

Migraine and Chorea.—Dr. de Schweinitz has never seen a cure of true migraine by the correction of refractive or other optical errors, but he has seen de-

cided improvement. Migraine can be improved by the removal of any peripheral irritations, and such as originate in the eye are especially important. He has never seen the cure of Sydenham's chorea. But this, like other motor neuroses, demands the correction of every possible source of irritation that may be producing evil effects on an erethistic nervous system. Undoubtedly chorea is due to injudicious schooling in many cases. An analysis of 275 cases of the affection shows that children suffering from it are in 75 per cent. of the cases sufferers also from hypermetropia. This points to the necessity for careful eye examination and treatment. At times physicians will be startled by the improvement that follows proper treatment of the eye. Habit chorea very often is entirely relieved by proper refraction. There is no doubt then that the cure of eye-strain makes distinctly for the happiness of mankind and, while there has been much exaggeration with regard to it, the effort must be to correct the exaggeration and not to limit the application of the important therapeutic principles that underlie it.

Hysterical Amaurosis.—This, in Dr. de Schweinitz's opinion, is one of the most interesting subjects for investigation still left for the ophthalmologist. Bilateral amaurosis is impossible to estimate. There are some fifty cases in the literature. As a rule it comes on suddenly and disappears during the course of the next few hours, or days. One well authenticated case, however, lasted for ten years. Periodic amaurosis also occurs and adds to the mystery of this affection. With regard to hysteria, a most characteristic symptom is the contraction of the visual fields of the still more characteristic symptom of tubular fields, which has been recently insisted on in Germany. In this, whether the field be taken at a distance of one meter, two meters or three meters, the diameter of the field is always the same. There seems to be in most of the cases of hysterical blindness a definite succession of events consisting of amaurosis first, then hemianopsia and finally gradual cure, or there may be amaurosis, central scotoma, then hemianopsia and cure. An unusual width of the field is sometimes seen which corresponds to the hyperesthesia so often noted in other sense organs and especially in the touch nerve endings.

Hysteria and Organic Disease.—Not infrequently hysterical symptoms are noted in connection with organic disease of the nervous system. In these cases hysterical symptoms may also be seen in the eye. The toxemias, as for instance that due to intoxication with carbon sulphide are particularly noteworthy in this regard. Sometimes the symptoms are so anomalous as apparently to point to disseminated sclerosis. Even brain-tumor may sometimes give manifestations which apparently point to hysteria and the possibility of an associated hysteria whenever there is any injury or pathological condition of the nervous centers must not be forgotten.

Headache and the Eyes.—Dr. John E. Weeks, continuing the discussion, said that many headaches are relieved by proper treatment of the eyes, but he had never seen migraine relieved. He had never seen chorea or epilepsy under any circumstances cured by refractive improvement. Habit chorea, especially with unilateral facial spasm, orbicularis spasm, or both, promptly yields to eye-treatment. It must not be forgotten, however, that certain headaches accompanied by tendencies to vertigo that simulate migraine may, just as the habit choreas, be cured by the correction of refractive and other optical errors. The improvement in these cases is so striking and so immediate as often to be a great cause of surprise and easily to lead people into the idea that some serious constitutional condition has been cured.

Retardation of Development.—Dr. Joseph Collins said that there is no doubt now that the failure to correct optical defects during early years may hamper education and retard development. This is one of the great benefits that the correction of eye-strain has brought with it. On the other hand, the exaggerated claims with regard to epilepsy, migraine and chorea are without foundation. One patient improved at the Craig Colony out of 67 shows how little may be accomplished by the correction of refractive errors, for if all 67 of these patients had been hit over the head with a club and told that it would probably do their epilepsy good more than this number would have been improved by that confessedly crude bit of suggestive therapeutics. As regards chorea, Dr. Collins considers that it is an acute infection and therefore there can be no possible hope of improving it by means of eye-treatment. Of 100 cases of true migraine investigated and treated from the eye standpoint, none were improved. On the other hand, very many cases of pseudomigraine have been improved.

Not Necessary to See Patients.—Dr. W. B. Marple said that the neurologists seem to have forgotten how much progress has come in recent years in the practice of ophthalmology. To listen to the neurological criticisms of the failure of the correction of eye-strain to relieve various serious nervous conditions no one would think that they had realized recent ophthalmological progress. It seems that it is no longer necessary even to see patients to diagnose the existence of eye-strain. One distinguished ophthalmologist has shown that all of the prominent writers of England and America who suffered from chronic symptoms of any kind were really the victims of eye-strain diagnosed *in absentia*.

Multiplicity of Prescriptions.—Dr. Marple said that one of the most unfortunate features of present-day prescribing of glasses for refractive errors is the number of times that some eye specialists consider it advisable to change their prescriptions. If, after refraction, the patient comes back ten days to two weeks later, with a report that he is not feeling better, the glasses are changed. This happens again and again, so that by the time patients have become convinced of the advisability of consulting some other ophthalmologist it is not an unusual thing to have them present half a dozen pairs of glasses that have been prescribed for them in scarcely more than as many weeks. It is evident that there is no need for this changeableness and ophthalmologists are evidently trying to remove symptoms by means of spectacles that must be treated in other ways. There are certain nervous symptoms sometimes attributed to eye-strain which are not only not caused by refractive or other optical errors, but are not even contributed to by eye conditions at all.

Overtaxing the Eye.—Dr. Herman Knapp said that overtaxing the eye, especially when it is not in normally healthy condition, may easily produce reflex symptoms outside the eye, or pathological lesions within the eye. Headache from eyestrain is in this way not an unusual phenomenon and even hemorrhage into the retina may be due to overuse of the organ when the blood vessels are in weakened condition. Dr. Knapp recalled a very instructive case which he saw about thirty years ago. The patient admitted that he had been overreading until finally partial loss of vision had occurred. The pathological condition present was hemorrhage into the retina. Careful inquiry into the patient's immediately previous history showed that he had stayed up most of the night before, as well as on several preceding nights, reading all about what he now called that "damn Beecher trial." Straining of the eyes will thus bring out the defects that might otherwise remain latent for a long period.

Asthenopia.—This may be, in Dr. Knapp's experience, of two kinds, simple or complicated. Simple asthenopia does not produce mental or nervous symptoms. The individuals simply get tired and then are no longer capable of using their eyes. This is due to a congenitally weak visual apparatus, which exists in about one-third of all persons seen. If asthenopia of low grade occurs in people of nervous organizations then their nervousness tempts them to use their eyes beyond the period of physiological fatigue and the consequence is headache and other reflexes.

Centers of Conception and Perception.—Dr. Knapp considers that with regard to the eyes and consequent backwardness in intellectual development the existence of separate centers for conception and perception should be remembered. Minds may be perfectly capable of translating perceptions into ideas and not conceive ideas in such a way as to connect them with others. A boy may not be able to get through the alphabet, yet may have quite a talent for mathematics. The memory center may be deficient and while in these cases of nervous defects in the brain there may also be defects in the ocular mechanism, the two conditions are by no means necessarily connected as cause and effect.

Dr. Gruening said that no ophthalmologist of any serious experience pretends to cure epilepsy or chorea, or any of the real nervous affection. The neurologists then in taking great pains to refute the possibility of such cures are really not attacking a favorite position of the ophthalmologist, but rather the corpse of certain ideas and hopes that overenthusiastic ophthalmology encouraged under mistaken impressions for a while, years ago. The whole of the evening's discussion then, in Dr. Gruening's mind, had been too much occupied with dead issues. There is no use in trying to compel those who deliberately exaggerate the supposed effects of ophthalmological treatment to adopt a more conservative position, since they are not willing to do so of themselves.

Hysterical Amaurosis.—The President, Dr. Andrew H. Smith, said that in certain cases of hysterical blindness there can be no question of malingering. In a case seen not long since the patient became suddenly blind after having had a quarrel with her husband. There was no question of feigning in the case, because she was the worst scared woman Dr. Smith had ever seen. She presented certain other stigmata of hysteria, which seemed to make it clear what the true condition was and a favorable prognosis was given. Total blindness lasted for 36 hours after which there was a gradual regaining of sight.

Migraine and Muscle Balance.—Dr. Smith said that in one case he had been taught the lesson of a possible connection and of the possibilities of therapeutic effects in muscular eye deficiencies and their correction. The patient suffered every three or four weeks from intense headache. Practically everything was tried without avail and recourse had to be had to morphine for relief from the pain. Gradually the dose of morphine had to be increased until it became evident that the patient, a comparatively young woman, was contracting the morphine habit. She suffered from a slight amount of internal strabismus. Dr. Smith had insisted on a number of occasions that she should have her eyes treated. She constantly refused. She could not be persuaded to go to an ophthalmologist. Finally, one day when Dr. Smith was called to see her because of the beginning of her usual attack of migraine, he brought an ophthalmologist with him and insisted that the operation be done at once. After some demurrer this was permitted. The strabismus was corrected. Since then there has not been a single attack of migraine nor any symptom of it. Before the operation for strabismus, practically all the classical symptoms of true migraine were present. While then in most cases migraine is not relieved by operative procedures on the eye, it is evident that in some cases unexpected relief may follow from operations that would ordinarily not be deemed curative. Ophthalmologists must, therefore, always be called in consultation in such cases and whatever ocular defects exist must be corrected. At times the consultation will be rewarded by a cure as unexpected as it is welcome to the physician and grateful to the patient.

CHICAGO SURGICAL SOCIETY.

April Meeting.

Metapneumonic Empyema.—Dr. Arthur Dean Bevan, at the April meeting of this Society, showed a young man who gave a history of pneumonia, and a metapneumonic empyema. A rib had been resected, and an empyema of the left side drained eight months before by another surgeon, after which the opening closed. This was followed by a reaccumulation of the fluid, and when he saw the patient the entire left side of the chest was full of pus up to the clavicle, and the apex beat was in the middle line. He took an X-ray view of the case, which showed fairly well the condition. There was a small discharging fistula in the third intercostal space, two inches to the left of the sternum, and through this a probe could outline the entire cavity. The patient was septic, and in bad condition. A Schede operation was done. An extensive U-shaped incision was made, and the soft tissues lifted up. A resection was made from the third rib to the tenth inclusive. This was done subperiosteally. After lifting up a very large flap, and after the resection had been made, he took a powerful pair of scissors and cut away all of the intercostal tissues, including the pleura, which was three-quarters of an inch in thickness. This U-shaped flap was drawn down and a tube as large as the thumb introduced to the apex of the cavity, and the flap stitched in position. Some gauze was also packed in. The operation was done January 7. The patient had some sepsis for about ten days after the operation—in other words, the temperature continued. However, his condition gradually improved, and within about four weeks after the operation, he outlined the size of the cavity which remained, and it was done in this way: He injected iodoform emulsion into the cavity, sealed the opening, and took an X-ray picture. The skiagraph showed a cavity which reached almost to the clavicle, it being a fine, ribbon-like cavity. After he had outlined this cavity with the iodoform emulsion, he put the patient at work blowing up an air-bag. This was responsible for the complete cure which had taken place, and the obliteration of this long, ribbon-like cavity that extended to the apex. This was the seventh or eighth Schede operation he had done, and it was the most satisfactory one of the entire group.

Appendicitis with Perforation of the Duodenum.—Dr. D. W. Graham reported this case, in a patient, aged thirty-seven years, and after detailing the steps of the operation that had been performed, as well as mentioning the death of the patient on the tenth day following operation, at the autopsy the appendix measured 11 cm. in length and was found to pass directly upward behind the ascending colon, its free end being adherent to the psoas muscle and lying behind the curve of the duodenum and attached to it. Six centimeters from the pylorus and on a level with

and 3 cm. to the right of the biliary papilla was a perforation of the posterior duodenal wall 3 mm. in diameter. He presented a specimen showing the relation of the appendix to the colon, the abscess cavity and the duodenum.

Amebic Abscess of the Liver, with Complication.—Dr. Graham also reported this case, and exhibited specimen. The patient was a man, thirty-seven years of age. The specimen showed (1) the large sloughing wound of the abdominal wall which had been preserved intact; (2) the adhesion of the liver to the colon, which represented the point where the abscess was partially evacuated through the colon wall before the operation; (3) the abscess cavity in the liver as large as a fist, notwithstanding the contraction that had taken place; (4) many small abscesses through the liver; (5) numerous ulcers in the mucosa of the colon, with sloughing undermined edges and intercommunicating by chanels underneath the mucosa, having all the characteristic features of amebic ulceration.

X-ray of Cervical Rib.—Dr. D. N. Eisendrath showed a skiagraph from a patient, fifty-six years of age, who consulted him on acount of recurrent hemorrhages apparently from the lungs. The skiagraph showed beautifully the cervical rib. As regards the origin of this cervical rib, the only way one could understand them was to consider them as a reversion of type of the mammalia toward some of the elementary forms. This cervical rib existed in reptiles. It must be regarded as an abnormal development of the anterior nucleus of the transverse process of the seventh cervical vertebra.

Adenoma of the Mucous Glands of the Lips as a Cause of Macrocheilia.—Dr. D. N. Eisendrath reported this case. He said that this condition consisted in an enormous thickening of either the upper or lower lip, or both, and occurred especially in scrofulous children, was very apt to relapse, and often very chronic in character. Microscopically, it consisted of an hypertrophy of the mucous glands, with an increase of all of the tissues constituting the lip, the connective tissue, blood vessels, etc. It also occurred at times in syphilis. Operation was successful, with no recurrence of the disease since its performance.

Empyema.—Dr. A. E. Halstead reported the case of a child, eight years of age, who had an extensive empyema of two years' duration. He resorted to extensive resection of the ribs, except the second one. He found difficulty in getting the cavity closed under the scapula. There was a high cavity which extended away up to the second rib, and so far as he knew, as he had not seen the child for a month, this cavity was still open.

Results in Abdominal Wall Suture.—Dr. Charles Davison read a paper on this subject. Some time ago he proposed the fastening of a longitudinal silkworm-gut suture in the fascia of the abdominal wall by terminal bowknots, leaving the ends of the suture protruding from the wound; the knots to be untied by traction on the exposed ends and the suture removed at the completion of the process of healing. A complete series of 41 consecutive cases with sterile primary union was reported at that time. The aim of this simple manipulation was to obtain all of the advantages and security of close and accurate suture of the individual layers of the abdominal wall, without the danger of suppuration incident to the use of catgut, and its pulpification and absorption, and without the dangers of irritation and sinus following the use of any permanent buried suture. The writer had used the tied longitudinal silkworm-gut suture in all clean laparotomies during the three years, 1901-2-3, with the following results: 178 cases with 7 infections or less than 4 per cent. of infections. Of these cases, 23 were emergencies, operated upon without previous preparation, with 4 cases showing infection, all limited to the subcutaneous fat. The remaining 150 cases had hospital preparation previous to the operation, with 3 cases of infection, or less than two per cent. of suppuration in the prepared cases. Of the writer's 178 cases of removable silkworm-gut suture, 131 had been followed up to the time of the preparation of this report. One case of spontaneous epigastric hernia operated upon by Mayo's method had a recurrence of hernia two inches from the old line of incision five months after operation; three-fourths of one per cent. of postoperative ventral hernias.

Dr. A. J. Ochsner said there were three elements which must be considered in the closure of abdominal wounds. First, accurate coaptation; second, an aseptic wound, and third, the absence of pressure necrosis. If these three conditions were carried out, it did not make much difference what suture material was used, or what particular method one employed, he would not get postoperative hernia. Last year he had approximately 740 abdominal sections, and of this number he did not think there would be a ventral hernia in which the three principles referred to were carried out.

Dr. D. N. Eisendrath had seen the method of Dr. Davison used very satisfactorily.

Dr. Wm. M. Harsha said he had used Dr. Davison's suture method in probably twenty or more cases. There had been no hernia in any of the cases he had been able to follow up; but the skin cicatrix had spread in some cases. He had had no case of infection. By this method it made the neatest and nicest scar when one removed the sutures.

Dr. C. C. Rogers had used the Davison suture in 18 cases, 5 of them being emergency cases, the others hospital cases, with one case of infection. In 13 there had been no hernia; the others he had not seen or heard of recently.

Dr. Carl Wagner had used the longitudinal wire suture in several cases, but had abandoned it on account of the wound in two cases having opened. He thought the wire was too stiff. Silkworm gut was preferable, for the reason that it was much smoother and more elastic.

Dr. E. Wyllis Andrews said that one virtue of the longitudinal silkworm-gut stitch lay in the fact that it was semi-rigid and semi-flexible, becoming molded to the tissues and not stretching.

BOOK REVIEWS.

TRANSACTIONS OF THE AMERICAN CLIMATOLOGICAL ASSOCIATION FOR THE YEAR 1903, Volume 19. Printed for the Association, Philadelphia.

THE present volume of transactions of the American Climatological Association contains some interesting data with regard to the influence of altitude upon heart disease, by R. H. Babcock, M.D., and some notes on the relation of neuralgia to altitude, by F. Savary Pearce, M.D. The subject of tuberculosis and its treatment by change of climate, with special reference to the open-air treatment, is discussed in a suggestive series of papers. An interesting article with regard to consumption is the susceptibility of the negro to tuberculosis, by Thomas D. Coleman, M.D., of Augusta, Georgia.

Another series of papers has for subjects complications of pneumonia, the treatment of pneumonia, thiocol in the treatment of pneumonia and the death-rate of acute pneumonia. On the whole the volume is of a practical character and all those who are interested, especially in respiratory diseases, will find much suggestive material in it.

Pediatrics (The Medical Epitome Series). A Manual for Students and Practitioners. By Henry Enos Tuley, A.B., M.D., Professor of Obstetrics in the Medical Department of Kentucky University. Lea Brothers & Co., Philadelphia and New York.

This series of medical epitomes deservedly enjoys a high reputation. The present volume contains an excellent summary of the most recent progress of our knowledge of children's diseases. It is small enough to be carried around in the pocket for purposes of consultation and yet complete enough to be helpful even to the experienced practitioners, and it contains a number of formulæ for infant feeding and data with regard to the development of children that cannot well be carried in the memory, yet must be at hand at certain times. While originally intended for students, the book would undoubtedly be of great service to practitioners whose duties give them much to do with ailing children.

System of Physiologic Therapeutics. Volume 7, Mechano-therapy and Physical Education, including Massage and Exercise, by John K. Mitchell, M.D., and Physiology of Manual Exercise, by Luther Halsey Gulick, M.D. P. Blakiston's Son & Co., Philadelphia.

This masterly series is now drawing to a close. Practically all the projected volumes have been published and we congratulate the editor, authors and publishers alike on giving the profession so valuable a series of manuals.

The present volume, we believe, should be available to every medical man. Too frequently are the procedures here outlined left to the osteopath and the "quack." It is a great privilege to have in a well-illustrated form a manual dealing so completely with the form of muscular exercise.

A very useful chapter on Corrective Manipulation and Orthopedic Surgery is given by Dr. James K. Young, and Dr. Walter Pyle adds a useful chapter on Physiological Methods in Ophthalmic Therapeutics.

The Therapeutics of Mineral Springs and Climates. By I. Burney Yeo, Professor of Practice of Medicine in King's College, London. W. T. Keener & Co., Chicago.

From the standpoint of the practioner of ample practice among a favored clientele the subject of health resorts is one of much importance. By reason of the lack of efficient presentation in numerous text-books, he makes it a point to spend his leisure in taking short trips to various health resorts and thus obtains a first-hand knowledge, which is of undoubted service to his patients.

Yeo has evidently done this and has further taken the pains to write it all out, as it were, putting down his impressions as he went along, and later revision and editing has given us this practical and very useful manual. It is thoroughly reliable and full and an exceedingly serviceable volume, particularly for European health resorts.

A Manual of Electro-Static Modes of Application, Therapeutics, Radiography and Radiotherapy. Second Edition. By William Benham Snow. A. L. Chatterton, New York.

This second edition is an amplification of the first. We can add that for the beginner the volume is an extremely useful one. The writer's optimism is in need of some measure of corrective, but we believe that thoroughgoing optimism in therapeutics, even if dangerously near the border of charlatanry, is necessary in many therapeutic procedures.

Immune Sera. Hemolysins, Cytotoxins and Precipitins. By Prof. A. Wassermann. Authorized translation by Boldnan. John Wiley & Sons, New York.

This is a fragment, but a very useful one, of lectures given by Wassermann on topics outlined by the title. There is little in the small volume of seventy-five pages not in more extended volumes, and it is assumed by the writer than much is known by the reader—but, on the whole, a serviceable fragment.

BOOKS RECEIVED.

The Medical News *acknowledges the receipt of the following new publications. Reviews of those possessing special interest for the readers of the* Medical News *will shortly appear:*

Studies from the Rockefeller Institute for Medical Research. Volume I.

Notes on Malignant Growths in the Insane. By Dr. J. R. Knapp. Illustrated.

Modern Ophthalmology. By Dr. Jas. M. Ball. 8vo, 820 pages. Illustrated. F. A. Davis Co., Philadelphia.

The Personality of the Physician. By Dr. A. T. Schofield. 8vo, 317 pages. P. Blakiston's Son & Co., Philadelphia.

A Manual of Fever Nursing. By Dr. R. W. Wilcox. 12mo, 236 pages. Illustrated. P. Blakiston's Son & Co., Philadelphia.

Organes Genito-Urinaires de l'Homme. By Dr. Henri Hartmann. Quarto, 432 pages. Illustrated. G. Steinheil, Paris.

Transactions of the Rocky Mountain Interstate Medical Association. 1903. 8vo. Illustrated. Salt Lake City, Utah.

Transactions of the American Pediatric Society, 1903. Edited by Dr. Walter Lester Carr. 8vo, 234 pages. Illustrated.

The Therapeutics of Mineral Springs and Climates. By Dr. J. B. Yeo. 8vo, 760 pages. W. T. Keener & Co., Chicago.

The Ophthalmic Year-Book, 1903. By Dr. Edward Jackson. 8vo, 260 pages. Illustrated. Herrick Book & Stationary Co., Denver.

First Report of the Tenement House Department of the City of New York, 1902-1903. Two volumes. 8vo. Illustrated. New York.

The Clinical Study of Blood Pressure. By Dr. T. C. Janeway. 8vo, 300 pages. Illustrated. D. Appleton & Co., New York and London.

Seventeenth Annual Report of the State Board of Health of Ohio, 1902. 8vo, 508 pages. Springfield Publishing Co., Springfield, Ohio.

Atlas und Grundriss der Lehre von den Augenoperationen. By Dr. O. Haab. 12mo, 303 pages. Illustrated. J. F. Lehmann, Munich.

The Meaning of a Modern Hospital. By Dr. W. Bruce Clarke. 8vo, 47 pages. Longmans, Green & Co., London, New York and Bombay.

EYE-STRAIN AND THE PSYCHOSES.[1][2]

BY CHARLES L. DANA, M.D.,
OF NEW YORK.

IN studying the influence of eye-strain upon the bodily functions, it is very necessary to know what is meant by this term. It is not found at all in works on psychiatry, and is not mentioned in all recent works on ophthalmology. It is, on the other hand, rather frequently found in medical journals and in semi-popular medical literature. The eye seems to be the only organ which is thus popularly associated with a strain; for we do not hear of ear-strain or tongue-strain, stomach-strain or kidney-strain. Nevertheless, "eye-strain" is a convenient word, and probably carries a fairly definite meaning to most minds.

As I understand the term, eye-strain consists of two kinds of straining. In one case it is the automatic effort of the midbrain and oculomotor nerves to adjust the eye in such a way as to overcome abnormalities in refraction, accommodation and imperfect muscular balance. This kind of straining is largely done unconsciously, just as a person with one leg shorter than another unconsciously adapts his posture and gait to the deformity. This is really an eye-strain proper; it does not involve attention or conscious mental effort, except casually. It is mostly subcortical and is a kind of spinal eye-strain.

The second kind of eye-strain occurs when the eye is more seriously defective, or the receiving apparatus of the brain is fatigued. Then the cortical centers are brought into play. The imperfect vision is appreciated with some sense of its defective working, and a distinct and fatiguing effort is made to supplement the ordinary mechanism of the eye, and a sense of this effort, to the point of distress, may result. This attempt may not be distinctly recognized as an effort for better vision, but only perhaps as something wrong, which requires adjustment. This is the kind of eye-strain ordinarily meant, I presume, when the term is popularly and correctly used. It will be seen that eye-strain of this second kind is really a brain-strain. And it seems to me that it is only this kind of strain which can do any widespread harm. As long as eye-defects are automatically regulated by the machinery of the oculomotor nerves and midbrain, there will be no serious consequences, any more than a person with a somewhat shortened leg will suffer much as long as the shortening is so slight that it calls for no voluntary effort to help each step along. At least, it is only when a patient's brain becomes seriously weakened or tired by some additional trouble that the ordinary limp may become a real discomfort.

The further inference is, in my opinion, that many, perhaps most, minor ocular defects *may* exist without doing any harm, the organ compensating perfectly, like a leaky heart. (Over 75 per cent. of school children have refractive errors.)

Since real eye-strain is a kind of attention or brain-strain, it is quite easy to understand that it can lead to disagreeable results along various lines.

My task is to inquire what influence this cerebral eye-strain plays in the psychoses, or morbid mental states.

There are two groups of psychoses: one includes the insanities, technically speaking, in which responsibility is lost or custodial care required.

The other includes the minor psychoses, which embrace those forms of morbid activity of the mind displayed in hysteria, the neurasthenic insanities, morbid fears, doubting manias, imperative impulses, and compulsive acts; also in dipsomania, sexual perversions, erratic types of character allied to paranoia, as well as various hypochondriacal and abortive melancholic states. These are often grouped as neurasthenia. But neurasthenia is a condition which, I think, is relatively rare, for most or many neurasthenias are only psychoses of a minor grade.

Now, with reference to the effect of eye-strain in producing the major psychoses. Alienists, I think, without exception, do not recognize eye-strain, even as a contributing cause. I cannot find any systematic writer who even refers to it. In the last edition of Kraepelin (1903), and in the monumental work of Ballet (1903), of 1,500 pages, no reference is made to the subject.

Some years ago, as Dr. Mabon, formerly superintendent of the St. Lawrence State Hospital, informs me, a serious attempt was made by a competent oculist to help or cure cases of insanity in the hospital under his care, by attention to the eyes. But the oculist failed. About six years ago Dr. Coikendyl made similar experiments at the Willard State Hospital, and claimed some successful results. I am not prepared to deny his success, but I know that the hospital physicians did not share his opinion as to the value of his work. Some years ago oculists were appointed to the State hospitals of New York, and have done good work in relieving obviously defective conditions, but not in curing insanity.

My own experience has made me watchful for

[1] Read before the New York Academy of Medicine March 17, 1904.
[2] Received for publication March 28, 1904.

eye-defects in psychoses and neuroses, for I was one of the committee appointed some sixteen years ago to investigate the importance of Dr. Stevens's views in regard to eye-strain in epilepsy and chorea. The results of my observations have been small. I have seen a few cases of eye-strain, however, with apparent bad results mentally, in students at the secondary schools, where the young men really work hard. In them it seemed as if the eye-strain really led to a kind of exhaustion psychosis. These boys did not get migraine, or headache especially, but there was actually brought on, by close application to books, a mental confusion and exhaustion, so that they simply could no longer read, or study, or remember. This condition was accompanied with some apathy and depression and lack of general interest, so that they no longer cared even for their outdoor sports and amusements. The eyes showed refractive errors and secondary muscular strain. Recovery came very quickly in most cases after rest and proper glasses. In one case only was the exhaustion so marked and prolonged that I feared the development of dementia præcox.

I must add that these cases are very rare in my experience; the eye-strain usually showing itself only in discomforting local conditions. Nevertheless, I believe it wise to have the eyes of psychopathic children, who do not study or who do study very hard, carefully examined.

Again, in men in the forties, who are applying themselves closely as teachers or at some clerical occupation involving fatigue to both mind and eye, presbyopia comes on insidiously, and sometimes a condition of mental depression and irritability amounting to a mild kind of melancholia may develop. Here, no doubt, the eye-strain plays a considerable part. But these cases, too, are rare.

With regard to eye-strain and the minor psychoses, I might say a good deal, but as what I call the minor or neuropsychosis is usually called "neurasthenia," I should be encroaching on the field of others.

I can only say that after sixteen years of watching, I have found hardly any cases in which eye-strain is an important and direct factor in establishing even a minor psychosis, though it modifies its symptoms and secondarily adds to the disturbance. For example, in the hysterical, paralysis of the ciliary muscles may cause microscopy, spasm may cause macroscopy and accommodative disturbances may cause polyopia.

Dr. Gould, in his biographical clinics, gives sixty-eight reasons why success is not always obtained in treating the eyes of these cases, and to this I can only say that success is generally obtained without treating the eyes. In fact, the visual function is largely automatic and spinal, and when the mind is a good mind, the visual machinery does not overthrow or directly and seriously affect it. When the mind is unstable, or the body weakened, cerebral eye-strain plays its part; and when the mind is unstable and the visual machinery is very poor, even spinal and midbrain eye-strain may do some harm.

This is all that my experience or study can add to this subject, and I am not sorry that, in fact, the results are so meager. Perhaps after all the most real psychosis connected with eye-strain is that shown by a group of enthusiastic oculists who have become obsessed with the idea that eye-strain forms the background of most pathological conditions, and, like Bishop Berkeley and his tar-water, think that the whole material universe is nothing and eye-strain is everything. With due respect also to my learned colleagues, I should suggest that "glassing" had become something of, at any rate, a minor psychosis. For if it is sometimes underdone, it is oftener enormously overdone, as witness the spectacular prosperity of our modern opticians. For my part, though, I heartily believe that eye-strain should be carefully looked after. I do not think that our mental balance and nervous well-being are so entirely at the mercy of slight defects in an organ that has been perfected by millenniums of use and misuse.

MIGRAINE AND SICK HEADACHE.[1][2]

BY COLMAN W. CUTLER, M.D.,
OF NEW YORK.

Migraine is clinically considered by most writers a paroxysmal neurosis, having as its chief symptoms headache and a variety of sensory manifestations, characterized also by heredity, periodicity, and commencement in early life. From another point of view migraine or sick headache[3] may be regarded as the manifestation of an unstable nervous organism, influenced in many cases by various peripheral excitations, and it may be assumed that these, or rather their anatomical bases, are frequently transmitted from one generation to another in members of the same family, and form the hereditary feature upon which stress has been laid as an essential characteristic of migraine. It is evident, also, that the periodic attack cannot characterize migraine, for periodicity does not exclude a constant cause. In Jacksonian epilepsy the cause is constant when it follows a fractured skull for instance, although the symptoms are in the highest degree periodic.

Much has been written, of late, on the subject and little has been added to our knowledge of the disease. The confusion that exists is increased by unwarranted dogmatism shown by writers who assume a certainty which the indefinite nature of the disease and the lack of all pathological data do not justify.

It is common to find sick headache in many members or even generations of a family handed down with fatalistic expectations of its inevitableness, as if it were a family skeleton or an ill-omened heirloom. These headaches are strikingly similar in detail, having as many points of resemblance as family features. For instance, it is common to hear that in a certain family the head-

1 Read before the New York Academy of Medicine March 17, 1904.

2 Received for publication April 9, 1904.

3 Gowers ("Diseases of the Nervous System," Vol. II, p. 853) says that sick headache is always migraine.

aches are preceded by visual aura of the same type, or that the headaches begin in the same part of the head, or that the gastric symptoms predominate. It is relatively uncommon to find any variation of the type of disease, such as alternation of epilepsy and migraine in other members of the family. Moreover, in the experience of the writer, migraine is not more common in families with bad ancestry, such as alcoholism, than in those which are above reproach, and this, also, differentiates it from epilepsy, which is recognized as a disease often replaced by other grave neuroses or other degenerative disease, and in its idiopathic form pointing pretty directly to a guilty ancestry. And, finally, few claim that epilepsy can be influenced by treating the eyes or other peripheral organs, while many cases of sick headache are so relieved. The point made is that migraine is distinct from epilepsy, and that it is directly hereditary with a similarity in families which points to a specific cause.

Now, the fact that ocular defects are handed down in families with great uniformity is so common in the experience of every oculist that it needs no especial proof. Astigmatism is not infrequently similar in kind and in axis; muscular faults are also passed on in the same way by parents. Putting these facts together, namely, the heredity of migraine of a fairly constant type, with the transmission of certain forms of ocular defects in members of the same family, the correction of which in some cases relieves the sick headache, and we have a fair basis for the assumption that sick headache, having all the clinical features of migraine, is often a reflex neurosis of ocular origin. No doubt there are many other sources of peripheral irritation—the pelvic organs, nose, digestion—which need not be discussed here.

The question I wish to raise is this: Is there such a thing as idiopathic migraine, or can we assume that where no peripheral cause is apparent, the fault is in our defective means of diagnosis? Two obstacles to a solution present themselves: (1) A mistaken or confused idea of migraine; and (2), imperfect methods of diagnosis. There are many sick headaches, which although periodic, occurring in many members of the same family, and having clinical features of a classical attack, can only be differentiated from a hypothetical true migraine by the fact that they follow some obvious peripheral cause, and are relieved when that is removed. But those who suffer in this way are subject to attacks from irritations disproportionately small. Thus, where a patient has sick headache, and is relieved by the correction of half a diopter of astigmatism, the fault is not with the eye primarily, but with the unstable nervous system which made him susceptible, and it is into this that migraine resolves itself. But the fact remains that the disease must be approached at the periphery and the hope of success increases as our diagnostic and therapeutic measures become more perfect.

This leads to the second consideration: There are in the experience of every physician, even the most sanguine specialist, many cases of inveterate sick headache which persist in spite of the most varied efforts, and which require the use of small doses of morphine to make the attacks bearable. Such cases occur, in part at least, in adults in whom the disease was neglected during its earlier stages, until the headache habit was formed. This expression "headache habit" seems useful, and does not beg the question.[4]

In some of these sufferers an early correction of some peripheral fault might have prevented the welding of the vicious circle. It not infrequently aids, even at a late date, but in other cases all attempts seem futile, and we are tempted to accept the visitation as inevitable, and to limit the treatment to the attacks.

I wish to protest against this attitude, as a weak confession of our incompetency, and I venture to assert that, as a knowledge of these cases is developed, hereditary migraine will be recognized as a reflex neurosis, consisting of an unstable organism excited by certain peripheral strains which themselves form the hereditary influences. The chief danger in the passive acceptance of the idiopathic idea is that we thereby relinquish all efforts to determine the exciting and removable factor in the etiology.

An attempt to determine the proportion of cases due to different peripheral faults would be difficult. All avenues should be tried in turn, beginning with the one in which the strain seems most obvious, but this apparent predominance of symptom is often misleading. Not infrequently sick headaches in which the digestive disturbance is conspicuous, turn out to be due to eye-strain, but there is apt to be a sequence of events which will be suggestive. Again in those who are anemic and worried, with insufficient sleep, the eyes will give out, but a correction of their defects will not relieve the symptoms unless the general hygiene is improved. In some obstinate cases it is possible that the periodic attacks are due to triacid intoxication, as is believed to be the case with cyclic vomiting, although the type of headache may resemble that helped by other treatment.

The site and character of the headache, and the presence or absence of visual symptoms such as scintillations and transitory amblyopia is of little value in diagnosis. It is often stated that an ocular headache begins in the forehead or temples, but it is often found in the occiput or the back of the neck, with some tenderness of that region, so that the patient states that he cannot lie on the back of his head during the headache.

It is very common to find a dull pain following eye work, not infrequently most severe on awakening, filling the intervals between the paroxysms. This may yield to glasses and the intervals grow longer, and in some cases the attacks may cease, showing that the condition was cumulative, and that both kinds of headache were due to a common cause; or the dull, or more constant pain may be relieved and the paroxysms may continue,

4 Gowers, *loc. cit.*, p. 839.

indicating that there is a double cause, or else that the periodic attack is a habit which remains after the cause is removed.

It will be seen that migraine should be studied statistically, not only with regard to its prognosis and the results of treatment, but as regards its natural history, and data to be valuable must contain information regarding the family history and the family anomalies of structure, as well as the character of the attacks and their relation to different kinds of strain.

When this is done there remains a broader and less definite consideration. Many patients respond to very slight excitation while others bear large burdens of uncorrected astigmatism or nasal obstruction or other peripheral strain with impunity, so that the vague personal equation is at the root of the trouble.

That the neuropathic tendency which includes epilepsy and other grave degenerative conditions also includes migraine as a frequent accompaniment is obvious, but it does not follow that the vast number of patients with sick headaches with all the earmarks of migraine, including the visual aura, paresthesia and aphasia, or their families, need fear the development of epilepsy. Many writers claim that so-called ophthalmic migraine, or the form associated with scintillating scotoma, transitory amblyopia, and not infrequently with paresthesia and aphasia, is often a precursor of epilepsy. In speaking of ophthalmic migraine, the disease sometimes called ophthalmoplegic migraine is not referred to, as that has nothing to do with migraine.

In order to obtain the opinion of a man whose experience with epilepsy has been enormous, I have asked Dr. Spratling, Superintendent of Craig Colony, for his views. He writes: "In my experience migraine is an exceedingly rare equivalent of epilepsy, and ophthalmic migraine is equally rare. . . . I have never seen such typical instances of it as have been described by Brunton." Dr. Spratling states that it is the custom in taking histories of epileptics at Craig Colony to inquire regarding the occurrence of migraine in the individual and the family.

Epileptics show the most varied structural anomalies, astigmatism and faults of the ocular muscles are among the stigmata of degeneration, but it does not follow that these defects in themselves point to a neuropathic tendency, for in a far greater number of cases they occur in average individuals—and this I believe to be the case with migraine.

It is a thankless task to attempt to define migraine. On one side the clinical picture overlaps what has been called sensory epilepsy, and on the other it merges insensibly into the many forms of sick headache or pseudomigraine. The feature which appears to characterize it in the eyes of neurologists is that true migraine is inseparable from a neuropathic constitution, of which it may be the only manifestation, and this dependence of a clinical entity upon a vague substratum which is a constant, leads to the assumption, which I believe to be unjustifiable, that the former is also always a constant, a part of the personality.

If periodic, hereditary sick headache is, in a given case, the chief manifestation of this neuropathy, or is associated with certain stigmata which are not unknown in generally normal or average people, we are forced to say that its classification first depends on its failure to respond to treatment, and until all measures have failed no case can be called true migraine, and even then we have as much right to believe that the fault is with our imperfect knowledge, as others have to state that because it is linked with permanent structural conditions, it is thereby a fixture. I do not refer to cases in families in which epilepsy or other grave neuroses are present. I merely desire to call attention to a rather naïve way of reaching a conclusion. If conclusions may be drawn from the descriptions of writers like Gowers, it does not seem probable that migraine very often occurs spontaneously, as is the case with epilepsy. The unstable organism, the gift of an ancestry which had failed to adapt itself to its environment, predisposes, but usually there is a story of stress of some kind in the individual, which precedes the attacks, and if this can be relieved or the environment adapted to the individual, the sick headache ceases. No doubt the neuropathic tendency remains and may manifest itself again in the same way or in other ways, but the condition is relieved even if, in the broadest sense, it is not cured.

It would not be necessary to dwell on this point except that many writers, especially of the French school, fail to make a clear distinction. They have taken the most complex forms of nervous disease, and by analysis have obtained all the phenomena composing them, which they group together with brilliant generalization, but they thereby ignore minor differences of type which are essential. In other words, sick headache may and often does form a part of the neuropathic constitution, but only by association with other factors, and it is justifiable to consider as true migraine cases which, because of their broader neurologic significance, are more often seen by the neurologist, and it may be wise to limit the name migraine to these cases. But the majority of cases of sick headache, periodic and hereditary, with or without aura, occur in average people and may be called benign migraine or simply sick headache, or secondary migraine, if, as I have stated, there is in most cases a probable causal factor to be sought. Or else we adopt the *reductio ad absurdum* of Moebius who says "The tendency to headache is a part of the degeneration which is inseparable from civilization."

New York School of Clinical Medicine.—It is re- staff of the New York School of Clinical Medicine, in staff of the New York School of Clinical Medicine in West Forty-second Street, has been effected. The full details of the changes have not as yet been announced, but it is expected that a complete faculty will be chosen shortly.

THE RELATION OF EPILEPSY, CHOREA AND OTHER MOTOR DISTURBANCES OF THE NERVOUS SYSTEM TO EYE DISEASE.[1][2]

BY B. SACHS, M.D.,
OF NEW YORK;
PROFESSOR OF NERVOUS AND MENTAL DISEASES AT THE NEW YORK POLYCLINIC; ALIENIST AND NEUROLOGIST TO BELLEVUE HOSPITAL; NEUROLOGIST TO MOUNT SINAI HOSPITAL, ETC.

THE special task assigned to me on this occasion is to discuss the relation of diseases of the eyes to those few functional nervous disorders which are characterized by motor phenomena. This would limit the consideration chiefly to the bearing of ocular disturbances upon the development and occurrence of epilepsy, of chorea, and of the convulsive tics. It is so easy to juggle with figures whether intentionally or not, that mere statistical inquiries have never been to my liking. Instead of offering you numerical data, I propose to state in conscientious fashion a few conclusions which have been reached after years of experience.

I wish I could assume the attitude of the judge who, after listening to long harrangues, has a right to say to the jury "No case," and thus cuts off all further discussion. Let us confess frankly at the outset that the dependence of these motor neuroses, to use a convenient term, upon diseases of the eye, has been greatly exaggerated. Cases in which such dependence could be satisfactorily shown to exist are very few indeed, and the cases in which these neuroses have been cured by treatment of the ocular condition are fewer still. There are so many loopholes by which fallacies in the argument may creep in, that unless one is very careful one's judgment is apt to be warped.

It is curious that the claim of a relation of ocular affections to epilepsy and chorea is maintained chiefly by American writers; by oculists and pseudo-oculists rather than by neurologists. In the larger monographs issued within the last ten years in Germany, in France, in England, and in this country, in which the subjects of epilepsy and of chorea have been exhaustively treated in a truly scientific spirit, mention is barely made of the influence of muscular insufficiency, of marked errors in refraction, or of any other ocular derangement upon the development of the nervous diseases which we are now considering. It must be well known to you that the Stevens Commission of Investigation,[3] appointed some fifteen or sixteen years ago by the New York Neurological Society, in a report which was signed by Seguin, Dana, Starr, Birdsall and others, stated in unmistakable terms, that after careful investigation of fourteen test cases, not a single instance could be cited in which the cure of a genuine epilepsy had followed the relief of any one of the many "phorias" with which the oculists are pleased to puzzle us. My own experience since that time, and I am certain the experience of the majority of the neurologists, has borne out the conclusions of that special investigation committee.

From time to time advocates of this special doctrine of the relation of the various phorias to epilepsy have appeared; such evidence as they have furnished appears to me to be wholly untrustworthy. In September, 1902, an article was published by A. L. Ranney on "Ten Instructive Cases for the General Practitioner Proving the Powerful Influence of Eye-strain."[1] It will not be necessary to controvert this article or to criticize each one of these ten cases, but the character of the paper is well shown by the first case which is put down as one of "absolute mental failure," and mention is made of the fact that a previous diagnosis of cerebral "softening" had been made in a man of forty-one years of age. No data are given to prove that any such cerebral softening existed, nor is any attempt made to state the possible cause of the cerebral softening. The man is said not to have visited his place of business or even paid his bills for six months prior to his examination by Dr. Ranney. He presented such serious symptoms as neuralgic attacks in the left eye and left side of the face for twenty years and also suffered "from flowing of tears over both cheeks in cold weather." (It is astonishing that some of us have escaped the cutting of our muscles during the past winter.) In view of these serious symptoms the author states he "could not divest himself of the firm conviction that organic brain disease existed and that the case was probably incurable." It does not matter what the nature of this "organic brain disease" was. Evidently the author thinks it sufficient to state that after "a graduated tenotomy of the left superior rectus muscle, as a step toward the correction of the four degrees of manifest hyperphoria, the patient, although he had been much troubled with insomnia before the operation, slept without awakening the first night after the operation," and the "absolute mental failure" of former days disappeared at once after this remarkable operation.

In a case of epilepsy which the author quotes with especial delight, it is stated in the history that the patient had been in the habit of having fits at intervals from nine weeks to four years; after the operation he had an interval of three years and eight months when the case was reported, and the cure is said to be due to the operation. Another one of these remarkable cases is that of a man who at the age of thirty, and never before, had three or four attacks (note the accuracy of the statement) of grand-mal. His ocular condition was treated and the attacks disappeared. As though three or four convulsive attacks in a man of thirty years proves the existence of a genuine epilepsy? In this entire article there is not a single case that will stand the test of scientific criticism, but since this same author finds that he can cure diabetes by the relief of eye-strain and endeavors to explain this cure by the fact that the "centers which control the movement of the

3 *Journal of Nervous and Mental Disease*, Vol. 14. New series 1889.

1 *New York Medical Journal*, Vol. 76, 1902.

eyes are situated in the medulla in close anatomical relationship with the diabetic center," whereas such centers are far away from the medulla, we can understand the value of such contributions to medical science.

I would not have referred to this paper if it had not been published in one of our prominent journals and if it had not been accepted by a large number of medical practitioners as evidence of the relationship between eye-strain and several of the more serious motor neuroses. It is surely to the credit of the best authorities on ophthalmology that they have taken but scant notice of these peculiar literary productions.

In the last report of the managers and officers of the Craig Colony for Epileptics,[1] dated October 1, 1903 (p. 46), the superintendent, Dr. Spratling, records the fact that Drs. Gould and Bennett were given the opportunity of carefully examining and fitting 68 patients at the Colony with glasses. While these gentlemen in an article of their own had laid much stress "on the enormous proportion of cases of injurious astigmatic and anisometropic defects among epileptic patients" they were given full opportunity to put their doctrines to a test.

Dr. Spratling gives a table in which he shows that out of the 68 cases only one derived any benefit in his disease while wearing glasses, and the table which he includes in his article is a most instructive one, which might well be read most conscientiously by all those who may in future be inclined to follow this line of work. To be sure, Dr. Gould said when the unsatisfactory results had been brought to his notice, that the results "did not affect the fundamental fact that in a certain proportion of cases the cause, or the contributing cause, may be, and is, eye-strain." He seems to regret that the younger epileptic patients have not had the constant attention of an oculist or an optician. If an author maintains such a purely unscientific attitude there is no good excuse for attempting to argue with him. When he is driven into a corner he simply attempts to fortify his position by announcing that "if proper glasses could be given as a preventive measure in young epileptics and the care of oculist and optician insured, I have no doubt that epilepsy could be warded off in a certain number of cases." Enough has been said on this subject to show that the theories advocated by these oculists with extreme views are entirely untenable.

While, as recent discussions have shown, there may be some doubt in the minds of those who are competent to discuss the subject of epilepsy, as to whether or not it be of organic origin, all are agreed that true epilepsy is a serious chronic affection of the nervous system, due to some deeply rooted changes, and that the effect of such changes becomes manifest early in the life of the patient; that the disease continues to exhibit its full force for many years increasing in severity, as a rule, and often brings about a deterioration of the patient's mental condition. That this deterioration may in part be hastened by the long-continued use of sedative drugs we must admit, but this has no bearing upon the consideration of our special subject. It is furthermore true that of all the cases of epilepsy only a relatively small proportion have been found to be curable by any known therapeutic measures, and if we may credit, as well we may, the recent reports of the physicians in attendance at the Craig Colony, the regular, systematic life of the inmates of that Colony contributes more to a cure or to a relief from the manifestations of the disease than any other agencies which have heretofore been employed.

If we wish to prove that epilepsy is due to some disease of the ocular muscles, or to some other disturbance of the eyes, the argument must rest upon evidence that such ocular disturbance has existed as long, if not longer, than the epilepsy itself, and that with the correction or the cure of the ocular trouble, the epileptic attacks have ceased. If we cannot produce such evidence, we can at most maintain that in a person who has from some other cause developed epilepsy, either through inheritance or possibly through early cerebral injuries, the ocular disturbance has led to individual epileptic attacks, just as in some persons predisposed to epilepsy the onset of an acute contagious disease might give rise to convulsions, as in others the presence of an intestinal parasite might do the same, or as in some others the accumulation of poisonous products in the gastro-intestinal tract might give rise to serious convulsions.

The question of paramount importance, however, is not what causes the individual attack, but what brings about the predisposition to such attacks, and in this instance the predisposition is the disease itself. A just inference from this argument is, that if an epileptic patient presents any marked physical disturbance, whether it be a nasal obstruction, a narrow prepuce, a discharging ear, whatever physical disturbance he may present, let that condition if possible be remedied, for it may be the exciting cause of the individual epileptic attack, but do not let us suppose for an instant that the existence of such physical condition is the actual cause of the epilepsy. It may aggravate the disease, but it has not originated it.

I am willing, therefore, to grant that it is but fair that the patient suffering from epilepsy should be given the advantage of most careful examination by a competent and unbiased oculist, and that errors in refraction, muscular insufficiency and the like, should be properly corrected. If we proceed one step further and ask whether these measures are generally successful in inhibiting attacks, I make free to answer that from my own personal experience I do not know of a single case in which the epileptic seizures have been altogether inhibited or even diminished in number by the wearing of glasses, by the cutting of muscles, or by any other ocular measures

1 Cf. Editorial in Medical News, March 19, 1904, p. 560, which appeared two days after this article was read, and independently of it.

which had been adopted. That this practice is frequently resorted to is attested by the fact that it is rare to find a case of chronic epilepsy, at least among private patients, that, in addition to the bromide acne, does not also betray the disease by the wearing of prisms. It is fortunate, indeed, for the patient, if he have not also some ocular palsy as the result of the overzealous care on the part of the oculist. I am fully aware that such zeal is founded, as a rule, upon an earnest desire to help the patient. But I have stated my own impressions rather bluntly, because as a neurologist I wish to elicit definite statements from competent oculists as to the actual benefits that have been derived to their knowledge from the treatment they have given epileptic patients.

If the ocular treatment of epilepsy were an entirely innocent affair, there would be little reason to protest against it, but in some instances more harm than good is done. I have in mind the case of a teacher who consulted me years ago, after he had been subjected to all sorts of treatment, including the cutting of his eye muscles. Up to that time he had been the victim of nocturnal epilepsy which had never interfered with his professional work. At the instance of some overenthusiastic friends, he was advised to abandon all previous treatment and to consult an oculist who promptly gave him the benefit of his surgical skill, which brought about no diminution of his attacks, but resulted in a double vision which was far more annoying to the teacher than the previous nocturnal attacks had been.

The confidence of some oculists has been so great that they have committed the serious error which the late Dr. Seguin pointed out many years ago, of abandoning all medicinal treatment and thus encouraging the occurrence of epileptic convulsions. There is surely no warrant for any such procedure; however confident the oculist may be, and I repeat there is little excuse for such confidence, it is well to continue the exhibition of drugs until the patient is well over the effects of surgical interference; then, by cautious diminution in the amount of bromides or of other drugs exhibited, let the oculist, if of unbiased mind, carefully determine whether the cutting of muscles or the wearing of glasses has been of any benefit whatever and if convinced that such procedure has not been beneficial, why not state frankly to the patient that he must resort to the old-fashioned medicinal treatment and not depend upon surgical procedures? A little conservatism in this matter will accrue to the advantage of the patient and to the ease of conscience of all honest oculists.

What has been said of epilepsy applies with equal force to the relation of eye-strain and other ocular conditions to chorea minor, or Saint Vitus' dance. Although the morbid pathology of chorea is still a matter of dispute, it is another one of the general neuroses, implying very serious disturbance of the nervous system. It follows upon severe shock, upon emotional strain, and its relation to acute rheumatism and endocarditis suggests that it may, at times, be of infectious origin. The idea that it might be due to some slight lack of adjustment in the ocular apparatus is too absurd to be considered even for an instant. The advocates of this theory may, perhaps, claim that ocular insufficiency may as well as not be considered one of the possible reflex causes of the disturbance, just as some overenthusiastic and unscientific physicians have occasionally attributed chorea minor to nasal obstruction or to some disturbance in the sexual sphere both of boys and girls, but even of this reflex origin of chorea there is very little sound proof. If true at all, it is only fair to say that the conditions just referred to may possibly prolong an attack of chorea, but I am yet to find a single case that furnishes indubitable evidence of the fact that Saint Vitus' dance was actually cured by the treatment of any one of these conditions.

There is, however, one other disease which, to my thinking, is entirely distinct from Saint Vitus' dance, but which bears a superficial resemblance to it, and may sometimes be caused by some eye-strain. This is the condition known as "habit chorea," characterized in some by blinking of the eyes, by curious movements of the nose and face, in fact, by all forms of grimaces. In others it is characterized by irregular movements of the shoulder muscles, of the head, the hands, or, for that matter, by irregular movements of any part of the body. This condition is apt to be a very chronic one and the name "habit chorea" is well chosen, for the impression that one obtains from these cases is that the habit is formed, although it may originally have been engendered by some special slight morbid condition. In these cases of habit chorea, I thoroughly believe that it is well to have the patient carefully examined for his ocular as well as for his nasal condition and any existing defect, however slight, remedied. It is these cases of habit chorea, and not cases of Saint Vitus' dance, that are relieved by such treatment as a competent oculist may suggest. It is hardly necessary to urge great care in this matter, for this special form of treatment has also been over-done. Little discrimination has been shown and choreic patients are wearing prisms very much more frequently than the condition would seem to warrant. Let a careful distinction be drawn between habit chorea and chorea minor.

Habit chorea and convulsive tic are, as far as the symptoms go, not very unlike each other, although the latter is a much more serious neurosis. Facial spasm, which is perhaps the best single example of convulsive tic, at times develops after some great emotional strain and is acknowledged by all to be rarely of reflex origin. Altogether, the more one examines into the reflex causes of well-known neuroses the more firmly is he convinced that it is always hazardous to attach undue importance to such etiological factors, and so I would consider it a sheer waste of time to attempt to prove or to disprove any bearing that an insufficiency of the ocular muscles might have upon the development of convulsive tic. Let

those who may be anxious to put this special etiological factor upon a high pedestal, furnish evidence of this relationship, the burden of proof rests upon them.

Summing up all that can possibly be said with due regard to truth, it may be stated that the relationship between ocular affections and epilepsy, chorea, and convulsive tic, may be a close one in the minds of some "faddists," but it must remain a very remote one in the minds of those who have no special axes to grind and no particular therapeutic territory to exploit.

21 East Sixty-fifth Street.

THE EYE SYMPTOMS OF HYSTERIA, NEURASTHENIA AND THE TRAUMATIC NEUROSES.[1][2]

BY WARD A. HOLDEN, M.D.,
OF NEW YORK.

THE functional eye disturbances found in neurasthenia and hysteria are not always characteristic of one condition or the other, since the minor eye disturbances common in neurasthenia are found in hysteria also. The eye disturbances of traumatic neurasthenia or hysteria do not differ particularly from those of the non-traumatic varieties. Hence in describing these symptoms it is not necessary to classify them according to the underlying neurosis or psychosis.

The morbid states which give rise to the symptoms we are concerned with are as follows: First, the cornea and conjunctiva may be anesthetic or hyperesthetic; second, the eye muscles may be relaxed from fatigue or, on the contrary, be in a state of spasmodic contracture; and, third, the visual perceptive apparatus may show signs of fatigue, while there may be also psychical perversions of visual perceptions.

We may perhaps best cover the subject in the short time at our disposal by describing the functional disturbances as they would be brought out in a routine examination of the eyes.

The patient's subjective complaints are mostly of pain and parasthesia in various parts of the head after using the eyes, of clouds or bright spots before the eyes, and of an apparent increase or decrease in the size of objects seen. Furthermore, after reading for a length of time the print may seem to fade away because the muscles of accommodation relax from fatigue, or the print may appear doubled because convergence cannot be long maintained, or the lines of print may seem to flutter and become confusing because of the duration of their after-images in the fatigued retinas is abnormally prolonged.

On inspection a fine tremor of the lids is always noticeable when they are gently closed. There may be lacrimation, although the eye presents no signs of inflammation, and also photophobia, which causes the patient to let the upper lids droop over the pupils. This droop occurs also as a symptom of fatigue as the examination proceeds, and to overcome it one must from time to time sharply admonish the patient to keep the eyes wide open. Sometimes this ptosis of one or both upper lids may be considerable, but it is easily distinguished from paralytic ptosis, and the patient not only may fail to raise the lid when directed to do so, but also may forcibly resist the examiner's effort to raise the lid with his finger. Besides this partial closure of the lids there may be complete forcible closure in one eye or both from distinct spasm of the orbicularis muscle.

The reflex closure of the lids when the cornea or conjunctiva is touched is frequently slow or wanting, indicating anesthesia of these parts; and this anesthesia is likely to be more pronounced in the eye having the more marked disturbances of vision or on the side corresponding to a general hemianesthesia.

The pupils are usually normal in size and in reaction, although in cases of hysterical blindness they may be large and unresponsive.

The extra-ocular muscles often exhibit a lack of balance and particularly a varying latent divergence or exophoria, which may be regarded as a sign of fatigue from convergence. Again, a spasm of any of these muscles may give rise to diplopia, which might suggest an actual paralysis, but the anomalous behavior of the double images in different directions of the gaze and the presence of corroborative symptoms lead us to the diagnosis of a purely functional disturbance. As an example of this I may cite the case of a girl of twenty years recently examined, who complained of having seen double for several days. The eyes converged slightly. She had homonymous diplopia with the images level and an equal distance apart in all directions of the gaze, a condition not to be explained by a recent paralysis. Furthermore, her corneas were anesthetic and her color fields contracted. A diagnosis of hysterical spasm was made. When examined two days later the muscles were in perfect balance and no diplopia could be elicited.

Diplopia of another sort and of a purely psychical nature is absolutely characteristic of hysteria and is a very valuable diagnostic sign when it exists. This is uniocular diplopia. With one eye closed the patient sees a light double, when it is carried a certain distance away from the eye, and when asked to count fingers he sees double the number presented. This symptom was of value in the case of a man of thirty-five years who came to the Vanderbilt Clinic three months ago complaining of failing vision. He saw $^{20}/_{50}$ with each eye, the fields of vision were concentrically contracted, the optic disks were pale, within physiological limits, and the knee-jerks were unequally exaggerated, all suggesting atrophy of the optic nerves. Two weeks later he returned with a new card and I saw him. The pupils were normal, the fundi were apparently normal, and retinoscopic examination showed him to be emmetropic. When asked to read the distant test letters he hesitated. His left eye was then covered and I held up two fingers 15 feet

[1] Read before the New York Academy of Medicine at a meeting held March 17, 1904, under auspices of Section on Ophthalmology.

[2] Received for publication March 23, 1904.

away from him and asked him how many fingers he saw with his right eye. He promptly answered four. When I held up four he said eight, and so on. When the left eye was used alone he gave similar answers. The sensibility of both corneas was found to be reduced. It was then learned that he was bringing a damage suit against a company for injuries he had received several months before. The only possible diagnosis was traumatic hysteria with functional disturbances of vision.

A similar case seen last week was in an intelligent girl of nine years, who had come to the Vanderbilt Clinic and obtained glasses correcting a low degree of myopia. She came back complaining of seeing lights in the distance double. I found that she saw a candle flame single in all directions of the gaze when it was held not more than 15 feet away. When held at a greater distance she said she saw two flames five inches apart and one diagonally above the other in all directions of the gaze. But when one eye was covered the double images were seen exactly as before—uniocular diplopia. Fingers were counted correctly at every distance. With a red glass before one eye while both were open she said she saw two red flames, but casting consistency to the winds, she averred that she saw a red and a white flame when a red glass was held before one eye while the other eye was closed. The sensibility of her corneas was reduced, but the color fields were normal, and her mother had observed no other evidence of neurotic or psychical disturbance. Her future history is likely to be interesting.

The acuteness of vision is usually normal, but the patient often reads the distant letters slowly, and with an effort, and only after considerable urging. There may be even more difficulty in reading small print near by, and the patient will hold the test card close to his face or far away or to one side, assuming cramped positions, and even repeated urging may not make him read the smallest print. But if an indifferent glass, plain, smoked or weakly refracting, is held before the eye the psychical effect is such that both distant and near vision at once become normal or as nearly normal as the patient's refractive condition will permit.

In rarer cases vision in one eye is very poor or the patient may be unable to see at all. But if we employ any of the tests for detecting simulated blindness, which all consists in arranging lenses, prisms or colored glasses in such a manner that the patient uses the eye with supposed poor vision while believing that he is using only the eye with good vision—we find that the sight of the poor eye is in fact normal.

For the still rarer cases in which there is apparent blindness in both eyes we have no test to reveal the actual amount of vision, but the diagnosis can usually be made from the presence of other hysterical symptoms, the previous history of aphonia and the like, and the lack of organic changes in the eyes. The patient, however, finds it too difficult to maintain this fiction long, and usually the vision which was lost suddenly, after a few days as suddenly returns.

Anomalies of the visual fields are the most frequent and the most characteristic eye disturbances in neurasthenia and hysteria. The typical condition if the examination is made deftly without overfatiguing the patient is a normal field for the usual white test object, a concentric contraction of the color fields in their regular order, and a diminution of central color perception in that a small area of color is not recognized as far away as by the normal eye. These anomalies of color perception are to be regarded as evidences of fatigue of the retina or of the psychical centers or of both. If the examination is tediously made or purposely long-continued, evidence of increased fatigue is manifest in further narrowing of the fields, giving them the watch spring or spiral type. That is, if the limits of the field are plotted a number of times continuously, the boundary line recorded will be a diminishing spiral.

Besides the typical concentric contraction of the color fields in their regular sequence there is occasionally a reversal of their sequence, the field for red being larger than that for blue, and occasionally a contraction of the field for white. But rarely is there a central defect in the field or a defect of a hemianopic type. The contraction of the fields is often more pronounced in the eye of the side which is more anesthetic. The size of the fields varies from day to day, and hence a repetition of the examination is often of assistance in making a diagnosis. In order to illustrate the fluctuation in the nature of the visual disturbance I may cite the case of a lady of twenty-five who complained of sudden loss of sight in the left eye. Tests for simulation showed that the left eye had in reality normal vision, and a week later the patient with this eye easily read $^{20}/_{20}$. Two weeks later, however, the vision of this eye had fallen to $^{20}/_{50}$, and there was a central scotoma for colors, which is so unusual in hysteria that if I had not observed the patient's previous symptoms I should have been inclined to diagnose a retrobulbar neuritis. A few days later vision was again normal.

The forms of the color fields in hysteria are sometimes so bizarre that they do not simulate those of any organic lesion, and the diagnosis is then easy. For example, I examined for Dr. Dana a lady with traumatic neurosis after a severe injury in a railway wreck, and found that she had normal fields for the left eye, and for the right the field for white was normal, as was also the field for a 3 mm. black dot on a white ground, the field for which is usually equivalent to that for blue. But with this right eye she perceived colors nowhere except in an area 15° in diameter, a few degrees downward and inward from the point of fixation, and in this area blue, red, and green were all recognized. When examined three weeks later the fields for white and for a 3 mm. black dot were normal in each eye, but colors were recognized only in the left halves of the field and in a small portion of the right halves.

In other words, there was an atypical right homonymous hemianopsia for colors.

It should not be supposed that these functional eye disturbances are common in young women only. Some of the most marked and most persistent disturbances are found in strong men with hysteria following injury or nervous shock, and I will conclude these remarks by describing an attack of hysteria major in a brawny mounted policeman aged thirty-six years. On November 9, 1902, he was thrown from a vicious horse and stunned, but he continued his work without interruption. Two weeks after his fall he began to hear voices while riding his beat, and the arc lamps along the suburban roads appeared, as he expressed it, "like great red bleeding hearts." On December 5, a month after his fall, he became wildly excited and dashing into the station house proclaimed with violence that he was the police captain in command. He was overcome with difficulty and taken to the Bellevue psychopathic ward. Here he continued in an excited state and complained greatly of pains in his head, which sedatives did not relieve. After three days he became rational, but was then unable to see, although his pupils were of normal size and responded promptly to light.

Five days after his admission I saw him and found his eyes so wide open and staring that the condition had been taken to be exophthalmos. The pupils were then large, the left larger than the right, and the response to light was rather sluggish. He had perception of light, but he recognized a candle flame in the nasal portion of each field only. The fundi were normal. Further examination revealed diminished hearing, diminished sense of taste on the left side of the tongue and left hemianesthesia, with some points along the spine so hyperesthetic that when they were pressed upon the patient nearly jumped from his bed with pain.

The staring look continued, the pupils responded sometimes promptly, sometimes sluggishly, and vision improved a little. After the patient had been observed and frequently examined by many physicians, Dr. Dana and others concluded that at that time he was suffering from pure hysteria, and after being kept two weeks longer in the general ward, he was discharged.

On January 31, 1903, seven weeks after his attack, at my request he came to my office for examination. He still had the staring look and could count figures with each eye at a distance of two feet only, and this only in the nasal portion of each field near the point of fixation. With each ear he could hear ordinary speech no farther away than three feet, although the tympanic membranes were normal. Sensibility was diminished on the left side of the body, taste was diminished, and he dragged his feet as he was led about. His condition gradually improved and six months later he was able to read. In January of this year, fourteen months after his attack, I found him in perfect health due, he thought, to his indulgence in violent physical exercise. His hearing was good, taste good, sensibility normal, vision had returned to $^{20}/_{20}$ in each eye, and the only sign of functional eye disturbance remaining was a marked tremor of the lids when they were gently closed.

His persistence in simulating this remarkable condition of the fields was perhaps attributable to the fact that its peculiarity had been much discussed in his hearing at the earlier examinations.

INTRAHEPATIC CHOLELITHIASIS.*

BY EDWIN BEER, M.D.,
OF NEW YORK.

By intrahepatic cholelithiasis is meant the production of gall-stones within the liver in the branches of the two hepatic ducts. In these intrahepatic ducts gravel or bile-sand and real calculi may be found together. In other cases, however, the calculi are found alone, while in still others the gravel or sand alone is present.

From a theoretical standpoint, both manifestations of cholelithiasis are important, but while the calculi seem to be of practical moment, bile-gravel seems, more rarely, to lead to symptoms. The calculi being the adult form of intrahepatic concretions and the gravel being the infant form, most of the remarks that follow, though applied to the calculi proper, will be equally true of the gravel concrements, but as will be evident, at times to a lesser degree, owing to the smaller size of the latter.

Intrahepatic cholelithiasis has been known for a long time and scattered through the literature of more than two centuries are lists of cases. I doubt, however, whether all these cases, the fruit of many years' collecting and observation, would reach a total of one hundred and fifty. The causation of intrahepatic stones, their frequency of occurrence and their other characteristics have received but scant attention, though occasionally authors, especially Körte,[1] have hinted that intrahepatic stone formation might be of vast import in the prognosis of cholelithiasis.

To study these relations I began the present investigation, and have examined a large number of selected cases, which I believe will throw some light on the frequency of occurrence, causation, structure and composition of intrahepatic calculi. That such an investigation is particularly timely, now that surgery is so frequently called upon to deal with gall-stones, no one can deny. Moreover, a recent article from Kehr's Clinic by Berger[2] and a more recent one by Kehr[3] himself, have suggested to me that this whole subject of intrahepatic gall-stones requires a careful study, and may be much more important than medical men in general believe. According to these writers, in the after-treatment of cases of common duct obstruction caused by stones, in an astonishingly large number numerous stones and fragments of stones were discharged from the drained hepatic duct. That all these stones and fragments were not of

* From the Laboratory of Professor Weichselbaum, Vienna.

intrahepatic origin seems likely, but that some were, can not be doubted. The great emphasis that Kehr and Berger lay upon getting rid of all these stones, if recurrence is to be avoided, shows at once how important is the whole question of the production of stones within the liver ducts.

A study of this condition throws light on a great many of the problems connected with cholelithiasis, both those of etiology and therapy. Moreover, an understanding of this condition must naturally have a bearing on prognosis.

A short review of the known facts on this subject is quite necessary. Stones were noted in the liver ducts in the eighteenth century, in fact, even earlier. Glisson found them in cattle, whereas others have described them in man. Morgagni[4] collected the known cases, but up to the latter half and the end of last century cases and facts have been very scarce. Frerichs[5] reports having seen five cases, and in view of his large experience, that is very surprising. Thudichum,[6] who attempted to find the nucleus of many gall-bladder stones in the liver ducts, reports that in five per cent. of the livers of patients suffering from cholelithiasis such stones occur. Most subsequent workers have either ignored or been unable to verify Thudichum's observations. These find that intrahepatic stones are not as frequent as he declared, nor can they with any regularity be traced to the gall-bladder, where they should grow, according to Thudichum, into the gall-bladder calculi. In 1891, Courvoisier[7] collected all the known cases, and in all found 50 in the literature. This meager number, which includes many cases in which gravel and not stones were found, gives a fair idea of the observations previous to that date, though scarcely of the frequency of occurrence of intrahepatic stones, as no investigator seems to have bothered about a systematic study of the question.

Since Courvoisier's statistics have been published, other cases have been reported, and in more recent publications of work along these lines, intrahepatic stones were found more frequently. Peters,[8] for instance, in 161 cases of cholelithiasis, found intrahepatic stones but once. Hünerhoff[9] in 85 cases of cholelithiasis found stones in the intrahepatic ducts once. Schroeder[10] of Strassburg finds intrahepatic concretions in nine per cent. of the gall-stone cases that he reported. The value of these three papers is very slight, as the work is in no wise personal. The papers are reports drawn up from autopsy notes which are spread over a great many years. Schroeder's work, for instance, consisted in looking through autopsy notes, and, judging from his paper, his cases which Naunyn so repeatedly cites, showed calculi only five times. The other eight cases, making his total of 13 or nine per cent., were gravel. The value of all such data is, to a great extent, lost, because the figures can not indicate what really existed, and what might have been found had the ducts in every case been carefully and systematically followed, and the etiological factors investigated. Niemer,[11] Kehr,[12] Riedel[13] and Lenhartz[14] have reported further cases, but no one seems to have looked into the question thoroughly. My results, based on such a study, will therefore be all the more interesting. In my series of 250 cases, I have found calculi five times, and once only gravel in the intrahepatic ducts. In a total of 72 cholelithiasis cases 8.3 per cent. showed intrahepatic stone formation.

These new data go to show that intrahepatic stone formation is not as uncommon as was once thought, and later it will be seen that under certain circumstances this intrahepatic production of stones is a more or less regular occurrence.

Before leaving the question of the frequency of intrahepatic stones, it would be well to state the views of Naunyn and Hoppe-Seyler, who seem to think intrahepatic calculi are even more common than the above data indicate. Naunyn[20] says: ". . . dass sie (Bilirubin-Kalksteinchen) häufig in den Gallengängen der Leber entstehen." Hoppe-Seyler seems to accept a similar frequency. On what these opinions are based I do not know, but they are strikingly in contrast with the other publications just cited.

The highest statistics so far published are those of Schröeder and myself. In eight or nine per cent. of cholelithiasis cases intrahepatic stones were found. (In Schroeder's statistics most cases were gravel.) As in general seven per cent. of corpses, or according to Schroeder's statistics twelve per cent., have gall-stones, intrahepatic stones might be present once in 160 or in 100 cases, respectively. That can scarcely be called a frequent occurrence. Under certain conditions, such intrahepatic calculi are found very frequently, but one might open many hundreds of livers, in which these conditions were not present, and never find a sign of intrahepatic stone formation.

The causation of these intrahepatic stones has always been very obscure. At first the process was explained as mechanical; later a chemical explanation was proposed. Frerichs[15], in 1858, opposed the purely mechanical views, saying that "the simple concentration of bile can not be looked upon as the cause of the precipitation of the substances that go to the formation of gall-stones. These substances remain in solution as long as the bile is unchanged—that is, until the bile had been chemically changed by the action of the gall-bladder mucus." "The beginning of the precipitation of pigment, cholesterin, bile sand, calculi and powder-like structureless deposits are found wherever the liver secretion becomes stagnant and the bile is decomposed." Thudichum,[16] though he thought intrahepatic stones more frequent, interpreted their formation in much the same way. He attributed the production of intrahepatic stones "to a disease of the bile and a partial obstruction of one or more of the biliary ducts. Courvoisier,[17] after reviewing the 50 cases that he gathered, came to no absolute conclusion as to the cause, though he was inclined to think that "obstruction to the flow of bile increases the chances of intrahepatic cholelithiasis." He adds, however, that this is not his own idea, and that in 1580 Caspar Meyer

had expressed the same view, with this in mind Courvoisier thought that in cases of choledochus obstruction, the condition should be relieved early to avoid a secondary intrahepatic production of stones.

In 1892 Naunyn added a new turn to the question of causation. He showed that obstruction, pure and simple, would not suffice, as the intrahepatic stones were made up in greater part of bilirubin and its oxidation products in combination with calcium. This combination never occurs in stagnant bile, if no other factors come into play. These other factors, he thought, were the direct "influence of the living mucosa of the gall-bladder." "Perhaps bacteria are at fault, for they readily wander into the biliary system, when stagnation is present, and cause oxidation of the bile."[18] Though Naunyn, in general, attributes some importance to the effects produced by the poisons of the bile in gall-stone production, he does not expressly state such a cause in this connection. This new factor was first outlined by him at the Tenth Congress für Innere Medizin, and later developed in his book. At the Congress, Mosler,[19] in the discussion, said that intrahepatic calculi must be interpreted as the result of cholangitis. He did not avow the direct action of the living tissue, nor emphasize the necessity of obstruction; nor did he advance any arguments for his statements or proof of them. More recently (1899) Hoppe-Seyler has to a certain extent combined the views of Naunyn and Mosler. He says intrahepatic stones are most frequent in cirrhosis hepatis and also when the common duct, or hepatic ducts, are obstructed by tumors, parasites, or calculi. In these latter cases, the infection of the biliary passages, *i.e.* cholangitis, and the formation of bilirubin-calcium stones, which he adds may become the nucleus of larger stones in the gall-bladder, developed side by side. Naunyn in a note was more guarded, saying: "Frequently one finds in those cases that have intrahepatic stones, general bile stasis throughout the liver, *e.g.*, in tumors, cirrhosis, chronic congestion."[20] Riedel,[21] in 1903, said that intrahepatic stones were rarely primary, but could develop secondarily after obstruction of the ductus choledochus by concretions.

Before closing this review, it must be stated that Charcot[22] attributed the presence of some of the intrahepatic stones, to wandering of stones from the gall-bladder into the ducts. Though Charcot thought of the possibility of stones passing from the gall-bladder through the cystic duct, and then up through the hepatic into the liver, he also acknowledged an intrahepatic development. These, he incorrectly stated, have "jamais . . . la structure radiée, les couches concentriques, ni les facettes qui distinguent les calculs nés dans la vésicule." In 1897, Langenbuch[23] expressed the identical opinion. He opposed Körte's interpretation of Sendler's[24] case,* saying that the stones that were found in the liver, were derived from the gall-bladder, and gained their intrahepatic position, perhaps as the result of aspiration by the liver. Langenbuch will admit the intrahepatic formation of minute bilirubin-calcium stones, but he draws the line at other stones just as Charcot did, without giving any valid reason for doing so.

That stones may occasionally wander into the right or left hepatic ducts and thence into the larger liver ducts when the choledochus is obstructed, can not be denied. Such a case, I myself have seen, finding two gall-bladder stones that had wandered into the first division of the left hepatic duct. But to apply that process to those cases in which the ducts throughout the liver are filled with a large number of stones, as in Sendler's and many other reported cases; or, when the stones are arranged, more or less like graduated beads, the smallest being far in the liver in the hepatic radicles, and the largest near the hepatic duct, is surely going too far. Stones that have wandered must present the shape and size, as well as the composition of the stones that are found in the gall-bladder. To these requirements the intrahepatic stones in all my cases, to be cited later, in no wise conform.

Most writers, on the other hand, have taken so little note of this interpretation, that in their reports no discussion of it or comparison between the gall-bladder and hepatic stones are found. The size of intrahepatic stones is usually smaller than of those found in the bladder; their shape often altogether different, being frequently ovoid, or more or less cylindrical. Their close relation to the walls of the ducts, in which one may find some soft cast-like stones, already composed of definite layers of pigment and cholesterin; their location in some peripheral part of the liver; all these facts preclude a general application of any such interpretation as Langenbuch's. The older stones, as well as some of the younger ones, are often distinctly facetted, and if many stones form in the ducts they seem to conform to the rules that obtain in the gall-bladder and are facetted.

This brief outline will give an idea of the many views that have been entertained, both as to the frequency of occurrence, and causation of intrahepatic stones. As Courvoisier said, the views found in the literature are extreme, and as this seems to be due to the fact that nobody has undertaken the regular examination of a large number of livers, both normal and abnormal, for this particular purpose the above-mentioned difference can be readily understood. Hofrat Weichselbaum kindly allowed me to dissect a large number of livers at his institute in Vienna, for which I take this opportunity to thank him very cordially.*

The livers were obtained after demonstration,

* Male patient, 50 years old. Sick on and off for two years. Pain in the right side. Vomiting—once icterus. One typical gall-stone colic. Developed an abscess in right hypochondrium which closed rapidly after incision, except at one spot, where biliary fistula persisted. One and one-half years later, chill, pain, icterus, vomiting. Bile discharged through fistula in very large quantities. Operation disclosed a gall-bladder full of stones. After discharging many stones the wound closed. Later it opened again as icterus and chill developed. Death occurred two and one-half months after last closure of wound. Autopsy showed a much contracted gall-bladder—several stones in the choledochus. A large number of small and large stones throughout the liver ducts. Some of these were facetted. Their size varied from that of a pea to a cherry-pit.

* Some of the earlier cases were studied in Prague. For the permission to use them I wish to express my thanks to Hofrat Chiari.

and the hepaticus branches were followed to the peripheral parts of the various lobes. Naturally the largest ducts alone could be inspected, and also only a small fraction of the whole intrahepatic duct apparatus, as the following of one duct into the liver substance destroyed many others that lay near it. In cases of obstructive jaundice, or cases of past obstruction of the common-duct, when the ducts were dilated, the following of the intrahepatic ducts is a very simple matter. In other cases, the size of the lumen of these ducts varies considerably, but only when the lumen is extraordinarily small does one find any difficulty. Even here it is readily overcome by practise and care.

In the 250 selected livers that I examined, there were 72 cases of cholelithiasis; of these six had one or more stones in the choledochus with secondary cholangitis. There were four cases of obstruction of the common duct, due to tumor, etc., and secondary cholangitis, without any gall-stones in the gall-bladder and large ducts. There were 71 cases of intrahepatic obstruction of the ducts, including metastatic tumors, ten; cirrhoses, thirty; abscesses, four; chronic congestion, twenty-seven. In addition there were amyloid and fatty livers, as well as normal organs.

SUMMARY OF THE 250 CASES.

	Times.		Times.
Cholelithiasis without complications	66	intrahepatic cholelithiasis	0
" and cholangitis, choledochus obstruction due to stone	5	do	5
" and old obstruction of choledochus due to stone (?)	1	do	1
Tumor or cyst obstructing choledochus and cholangitis	4	do	0
Metastatic carcinoma of liver	10	do	0
Cirrhosis hepatis	30	do	0
Abscess-pyelophlebitis	4	do	0
Chronic congestion	27	do	0
Atrophic-fatty-amyloid livers	39	do	0
Normal livers	64	do	0
	250		6

The six positive cases, as well as the four cases of common-duct obstruction, with secondary cholangitis, are briefly described below:

Case I.—Cholelithiasis, Choledochus Obstruction, Cholangitis, Intrahepatic Calculi and Gravel.—Female; no history obtainable. Autopsy showed very marked distention of the extra and intrahepatic ducts exclusive of cystic duct, chronic cholecystitis, with stones in the gall-bladder, two large calculi in choledochus and hepaticus. These were intensely inflamed and ulcerated. In the distended intrahepatic ducts throughout the liver several hundred calculi and a great deal of gravel. Stones and gravel were yellow in color. Similar deposit about the gall-bladder, and extrahepatic duct stones. The size of the intrahepatic calculi varied from that of a pin-head to that of a cherry pit. Many stones already show signs of facets—some of the larger stones are regularly tetrahedral. Most, however, are ovoid or spherical in shape. The intrahepatic calculi are smaller than the extrahepatic. In the latter is found an almost pure cholesterin nucleus about a central pigment mass, and as said above, this nucleus is covered by a yellow shell of pigment calcium. These nuclei are of the same size in all the extrahepatic stones, and are, in size, larger than the largest intrahepatic stones, which contain no such nucleus, and are almost a pure pigment calcium combination. The liver otherwise negative.

Case II.—Cholelithiasis, Choledochus Obstruction, Cholangitis, Small Black Sand-like Concretions in the Intrahepatic Ducts.—Male, 67 years old; no history obtainable, as patient was admitted moribund and markedly cholemic. Autopsy showed stones in gall-bladder—one stone impacted at papilla. Catarrhal cholangitis, but no pericholangitis. Contents of ducts muco-pus and bile with many small black concretions. Liver otherwise normal.

Case III.—Cholelithiasis, Choledochus Obstruction, Cholangitis, Intrahepatic Calculi and Sand.—Female, 27 years old; four or five weeks fever and icterus; well previously. Autopsy showed six stones in choledochus, which was full of pus; several stones in the hepaticus, multiple abscesses in the liver. In the intrahepatic ducts, numerous calculi and small sandlike concretions. Of the calculi, one was distinctly tetrahedral and as large as a grape pit. All were black. Soft calculi arranged in layers of pigment and cholesterin were found fitting like casts in the intrahepatic ducts. Liver otherwise normal.

Case IV.—Cholelithiasis, Cholecystitis, Choledochus Obstruction, Cholangitis, Intrahepatic Calculi and Gravel.—Female, 66 years old; three and one-half months before death, pressure in epigastrium and occasionally pain, anorexia, frequent vomiting towards evening, stool normal, marked emaciation, no icterus, slight fever (perhaps due to pleurisy) on one day, liver slightly enlarged, gall-bladder region tender, urobilinuria, ten days prior to death icterus developed. Autopsy showed acute inflammation of the gall-bladder, obstruction of choledochus by three stones. Ducts contained pus and erythrocytes, cocci, bacilli, epithelial cells and a large number of non-facetted, hard, yellowish red calculi almost as big as cherry pits (bearing no resemblance to the extrahepatic calculi); also gravel. Liver otherwise normal.

Case V.—Cholelithiasis, Cholecystitis, Choledochus Obstruction, Cholangitis, Intrahepatic Calculi and Gravel.—Male, 65 years old; pain, colic and tenderness in upper abdomen; sick in all about four weeks (anamnesis very inadequate). Autopsy showed general icterus, perforation of the gall-bladder due to ulcerative cholecystitis, four stones in gall-bladder, stone in choledochus, which was filled with pus. Intrahepatic ducts well dilated, containing about 30 pure black pigment stones, most of these a little larger than the head of a pin; one stone elongated, and almost a centimeter in length. Pus and fine pigment particles also present in intrahepatic ducts. Liver otherwise normal.

Case VI.—Gangrene of Lung, Cholelithiasis, no Icterus, Intrahepatic Calculi, no Cholangitis.—Male, 79 years old; history contains nothing about cholelithiasis; patient septic on admission; no icterus. Autopsy showed enormous dilatation of the choledochus, so that at first it was mistaken

for an accessory gall-bladder. No obstruction noted by the prosector. In left lobe two calculi as large as cherry pits, one distinctly facetted and the other well rounded; both yellow in color, with streaks of black pigment. All intrahepatic ducts much dilated. Several stones in the gall-bladder much larger than those in the liver. Liver atrophic. No cholangitis.

Case VII.—Carcinoma of Pancreas, Cholelithiasis, Cholangitis, no Intrahepatic Calculi, Obstructive Jaundice.—Male, 44 years old; no history obtainable. Very marked distention of the common, hepatic, and intrahepatic ducts. Pus in all ducts; no pigment masses, concretions or calculi.

Case VIII.—Carcinoma of Papilla, no Cholelithiasis, Obstructive Jaundice, Cholangitis, Multiple Small Hepatic Abscesses, no Intrahepatic Stones.—Male, 56 years old; eleven months before death had choledochus obstruction and cholangitis; three months later improved so that he could eat and work; no fever and only slight icterus during this period of remission. Five months ago a new attack of choledochus obstruction and cholangitis, which led to his death. Autopsy showed enormous distention of the common, hepatic, and intrahepatic ducts. All filled with pus; no sand or calculi found. At papilla, moderately large obstructing neoplasm.

Case IX.—Papillary Carcinoma of Gall-Bladder, Metastases in Choledochus, Obstructive Jaundice, Cholangitis, no Cholelithiasis, no Intrahepatic Calculi or Gravel.—Male, 74 years old; occasional pains in abdomen, during past four years. Five to six weeks before death had cutting pain in right hypochondrium. This came in attacks. Three to four weeks before death, pain became more severe, and chills began. Progressive emaciation. Never vomited spontaneously. No previous history of gall-stones. Autopsy showed a primary carcinoma of the gall-bladder, without any stones. A metastasis in the choledochus, and a dilatation of the ducts behind the obstruction. In choledochus, etc., and intrahepatic ducts, no calculi or gravel. Multiple abscesses in the peripheral parts of the liver, especially in the left lobe. Pus throughout intrahepatic ducts.

Case X.—Suppurating Echinococcus Cyst of Liver, Obstruction of Extrahepatic Ducts, Catarrhal Cholangitis, Chronic Cholecystitis.—Female, 27 years old; six months before death noted a tumor in right hypochondrium; no tenderness or pain, no colic, no vomiting nor icterus. Tumor was smooth, and seemingly of liver origin. About five months ago, gradual onset of icterus; no nausea or vomiting. Was able to continue work. Four to five weeks before death severe pains in region of tumor; no colic or cramps. Pains did not radiate. Never passed stones. Stools at first acholic, later somewhat colored. Temperature while under observation showed daily afternoon elevations. Autopsy showed a suppurating echinococcus cyst in the neighborhood of the porta hepatis, with considerable cicatricial tissue about its wall. Both processes obstructed the hepatic and common duct, and produced a moderate dilatation of the intrahepatic ducts. Mucosa of these, and of the hepatic duct, very much injected, and covered with tenacious mucopus and bile. No sign of stone formation. No gravel or calculi. Gall-bladder showed thickening of its walls and contracted lumen. Evidently the chronic cholecystitis had not led to gall-stone production.

In all these cases intrahepatic stones were found six times, and only in those cases where extrahepatic cholelithiasis was present. In all the other cases my search was in vain. Of the cholelithiasis cases only those that had or had had an obstruction of the choledochus by stones and secondary cholangitis showed intrahepatic stones. Cases of cholangitis secondary to tumors obstructing the common duct without extrahepatic cholelithiasis showed no intrahepatic stones. Moreover, all the other cases were negative, showing that the occurrence of intrahepatic stones of intrahepatic origin must be attributed to at least three different factors, obstruction, cholangitis, and a third unknown factor, otherwise, the obstruction of the common duct and secondary cholangitis, in the cases of tumor of the papilla and pancreas, etc., would have led to the formation of stones within the liver.

Similar cases in the literature I should not like to make use of, as the cases often lack important details in the various publications, and there is no guarantee that a thorough search for stones was made.

Just the nature of this third factor need not be discussed here. It must, however, be emphasized that choledochus obstruction, by stone, when followed by a cholangitis, leads to intrahepatic stone formation. On the other hand, cases of cholangitis in non-cholelithiatic patients do not develop intrahepatic stones. Whether this will be found true in a more extended experience time must show. Cholangitic material is very scarce, even at such an institute as that of Professor Weichselbaum.

The stone production seems to be just as likely to take place whether the cholangitis is severe or moderate, which is opposed to the present conceptions based on the work of Mignot,[25] Miyake,[26] and others. These experimenters showed that a mild infection of the gall-bladder by different bacteria frequently led to the formation of gall-stones, whereas a severe cholecystitis was fatal before stones formed. In the livers in my cases the ducts were several times full of pus and desquamated epithelium post-mortem, and once already noted at operation, when the choledochus was incised. Still, stones had developed.

It is well known since Netter and Homen's[27] experiments, that obstruction of the common duct leads to infection of the more central branches of the biliary system. Coli communis, staphylococci, streptococci, etc., wander in, and a more or less extensive cholangitis results. On post-mortem material such as I had, it is impossible to determine which bacteria are at the bottom of the trouble. As von Mieczkowski's[28] work has shown,

the post-mortem bacteriological examinations of the biliary passages lead to great errors. L'Etienne found, in 24 out of 42 normal cases, bacteria in the bladder bile obtained post-mortem, whereas von Mieczkowski, obtaining the bile directly from the aspirated gall-bladder during laparotomies, found it sterile, in the 15 cases examined.

The reports of Kehr[29] and of Riedel[30] are particularly valuable, as they worked with fluids in cholangitic cases obtained during life. In nine cases of choledochus obstruction reported by Kehr *bacterium coli* was present seven times, *streptococcus pyogenes* (*longus*) twice, and *staphylococcus pyogenes aureus* twice, in the bile discharged from the drainage tube. In every case the flowing bile was infected, agreeing thus in the main with animal experimentation, *i.e.*, ligation of the choledochus. Riedel's statement is very much to the same effect. In cases of stone in the choledochus causing obstruction, he found in 30 per cent. of 53 cases that there was infection of the gall-passages. Even this estimate is probably too low, judging from the animal experiments in which obstruction of the choledochus led almost regularly to cholangitis. My cases agree very well with the experimental work in the regularity of the development of cholangitis after choledochus obstruction. As experimental work has shown that the kind of micro-organism does not affect the chances of stone production, and as the same varieties are almost constantly present in cholangitis cases, one can not explain the non-formation of stones in cases (VII, VIII, IX and X) of tumor plus cholangitis, by supposing this series of cases to be due to different bacteria, from the other series, in which stones developed.

Another important factor is the time in which stones develop. Hansemann[31] only a few years ago said that nothing is known about this, but since then stones have been repeatedly produced artificially. Homens (cp. Hansemann) had noticed the formation of stones about sutures in the gall-bladder in one and two-thirds years, and Hansemann says he saw a similar case of stone formation in the duodenal wall about a silk suture in seven months. Since then stones have been produced experimentally in one-third to one year. Naturally, in these cases, stones were present even earlier, though smaller in size. In one of my cases I found a tetrahedral stone in the intrahepatic ducts four to five weeks after the commencement of symptoms of obstruction and cholangitis (Case III). Within two months, making allowances for all discrepancies in the anamnesis, stones can develop, and, in this case, a stone the size of a grape pit was found. Thus the element of time will be a factor in the production of intrahepatic stones, in cases of cholangitis.

In the cases (VII-X) of cholangitis with obstruction due to neoplasm, etc., the absence of stones, or gravel, in the ducts could not, however, be due to this factor, as, according to the history, and the evidence furnished by the liver, the obstruction and cholangitis had existed for weeks.

It is thus evident that stone obstruction of the common duct, plus cholangitis, often leads to intrahepatic stone formation. Many cases, however, can be found in the literature, of just this complex, without mention of intrahepatic stones. Whether following the ducts would have shown stones in these cases, it is impossible to say, but the frequency with which I found them seems to point to that conclusion.

In my positive cases, I had one in which stones were found, but no cholangitis was present (Case VI). Some of the largest stones, the size of cherry pits, were in this case. The history of the patient was incomplete, but at autopsy, an enormous dilatation of the choledochus without icterus was found. Stones were in the gall-bladder, and two stones deep in the left lobe of the liver. No signs of cholangitis existed. The stones were of good size and they had been there some time, as was shown by their size and close relation to the duct in which they were found. The dilatation of the biliary passages pointed to an old obstruction. The stones in the gall-bladder, which bore no resemblance to those in the liver, were a ready explanation of the obstruction, and, I think, knowing how regularly an infection follows impaction of a stone in the common duct, that it is justifiable to conclude that in this case a secondary cholangitis led to the stone formation in the liver ducts. The cholangitis subsided as the stone in the common duct passed into the bowel. The choledochus remained hugely distended, some stones were left in the liver, while probably many similar ones had passed into the bowel. Many of the cases in the literature are probably just like this one. Many stones are found in the liver at autopsy, but no cholangitis is present at this time. The ducts are dilated, showing an old obstruction, and the cause of the whole process has been passed into the bowel. In my case, the stones were altogether different in shape, size, and constitution from those in the gall-bladder, so that no chance of an extrahepatic origin of these calculi can be considered. In Czerny's case of chronic obstruction of the choledochus, lasting some 14 years, a similar condition seems to have been present. In this case, which I cite in brief below, as it is an excellent example of these cases, the ducts in the liver were filled with stones.

Case XIII of Mermann's[32] paper on Czerny's cases. J. O., 42 years old; had passed stones through bowel. For 14 years had been getting more and more icteric. Repeated Carlsbad treatment without any benefit; rather, perhaps, increase in jaundice after these "cures." Operation disclosed nine stones in the gall-bladder. Autopsy showed much distended choledochus which was filled with stones of hazelnut size. The hepatic ducts and their peripheral branches in the liver were much dilated and filled, far into the liver, with calculi, which varied in size with the lumen of the intrahepatic ducts, getting smaller the deeper in the liver they were found. The smallest were no larger than small seeds."

Before describing the stones that I found, and

the results they may lead to, I wish to mention the cases of Courvoisier and of Kehr. In a great many of the reported cases, the authors fail to say whether their patients had suffered from cholangitis, jaundice, extrahepatic cholelithiasis, or not, so that it would be useless to attempt a statistic on such unsatisfactory data. It is, however, noteworthy, that in the cases up to 1890, Courvoisier found cholangitis in 15 out of 52 cases of stones in the hepaticus and its branches.

From the above remarks, based on my cases, and the examination of Kehr's, and other reports, the fact that cholangitis is a most important factor in the production of intrahepatic stones can not be denied. Kehr has published a large number of cases of hepaticus drainage, and in a large percentage during the after-treatment stones and fragments of stones were discharged through the drainage tube. How many of these stones were of intrahepatic formation and origin it is difficult to say. In cases that discharged a large number of stones during the after-treatment, which Kehr could not feel in the ducts at operation, it is likely that an intrahepatic production of stones took place, and that these stones were derived from the intrahepatic ducts; the same applies to those cases in which numerous calculi were discharged for many days after the operation, as one would expect the calculi that had escaped the operator's finger to be discharged early, provided they were extrahepatic.

Now, looking through his cases and carefully considering these points, amongst the 17 cases that showed such a discharge of numerous stones after operation, and for a considerable time, there are at least six, perhaps seven, which seem to me probable cases of intrahepatic cholelithiasis.

To avoid any misunderstanding about these cases, I quote them below, abbreviating as much as possible the original publication, but giving all the essential points in the author's own words:

KEHR'S CASES.

Case XI.[33]—E. W., fifty-one years old. History of long standing cholelithiasis with frequent attacks of colic and jaundice. Six weeks before operation a severe attack—jaundice persisting. Fever for a few days. Another attack two weeks before operation.

Diagnosis—Choledochus obstruction due to stone. Cholangitis.

Operation—Choledochotomy. Hepaticus drainage. May 6, 1901. Gall-bladder very small. Contains no stones. Choledochus markedly dilated and contains two large and about 200 small stones. Hepaticus contains foul smelling, turbid bile, mucosa is gangrenous. In branch of hepaticus a calculus is impacted which can not be loosened.

May 7—300 gm. bile discharged. Still malodorous.

May 9—No bile discharged.

May 11—Icterus more marked. Stool probably contained bile on day before this.

May 14—Irrigation of hepaticus and choledochus. Many stones were washed out.

May 16—20 stones from the hepaticus, two of the size of hazelnuts.

May 17—A stone of the size of a pea washed out, otherwise the hepaticus is free.

May 22—Small sandy material washed out.

May 27—Washed out small fragments.

Sept. 13—Wound closed and patient in good condition, but three months later (*Berger, Langenbeck's Arch.* 69) discharged two more small stones and fragments. Later colic, icterus, chill, which were followed by death within two weeks.

Case XII.[34]—J. Sch., thirty-four years old. History of stomach trouble of several years' duration. Six years before operation colic, icterus, vomiting. Repeated colics since then. Seven weeks before operation very severe colic lasting ten days. Marked icterus. Since that attack, repeated mild colics. Emaciation.

Diagnosis—Stones in gall-bladder. Probably stone in choledochus.

Operation—Ectomy, Choledochotomy, Hepaticus drainage. August 21, 1900. Many stones were found in gall-bladder. Stone in cystic duct which reaches into choledochus. No other stones in choledochus. Bile flowing from hepaticus is turbid.

Sept. 2—Irrigation of hepaticus brought away small stones.

Sept. 3—No further stones. Discharged cured. But (*Beiträge zur Bauchchirurgie*, 1902, p. 98) four weeks later a severe colic and vomiting. Scar gave way and bile discharged. Colics returned every four weeks. After these slight icterus. On June 4, 1901, severe attack.

Diagnosis—Stone in choledochus.

Operation.—Duodenotomy (McBurney). Removal of a pea-sized calculus in papilla.

Epicrisis—Stone in the duodenal papilla overlooked at first operation.

Case XIII.[35]—Female, fifty-four years old. Operated February, 1893. Cholecystostomy. One stone found.

One and three-fourths years later again colic and icterus. Passed a stone which contained a silk thread.

One year later (October, 1895) had cholangitic symptoms. Again cholecystostomy. Bladder contained foul bile, and one stone with silk suture as nucleus. Patient improved, but continued biliary discharge pointed to choledochus obstruction. Operation disclosed stone in common duct, but it broke into pieces before it was removed. Abdomen closed, as nothing else was felt. Fistula remained open one-fourth year. Bile flowing, so that obstruction still persisted in choledochus. Shortly after refusing operation, fistula closed without pain. No stone in stool. About one-half year later, having been well during this period, suddenly fierce colic and icterus. High temperature, liver tender, pulse rapid, etc.

October, 1896, gall-bladder opened. Purulent bile and no stones in it. Choledochotomy showed large stone. Irrigation of ducts (hepaticus and choledochus) brought to light a mass of concretions. Irrigation continued for one-half hour.

In after-treatment a large quantity of similar fragments were discharged through the drainage tube.

Case XIV.[36]—F. Str., forty-eight years old. *History*—Two years before operation colic, icterus, vomiting, chill. Three months before operation another severe colic. This recurred frequently of late, and three weeks before operation a particularly severe attack.

Diagnosis—Cholecystitis. Stone in choledochus. Pericholecystitis.

Operation—Ectomy. Choledochotomy. Hepaticus drainage. June 17, 1900.

Gall-bladder is large. Contains many small stones, and turbid sero-bile. In choledochus and hepaticus about ten stones. Bile in ducts foul and turbid.

June 27—Hepatic duct sounded, two pea-sized stones washed out.

July 1—The sound feels a stone in the hepatic duct.

July 2—This stone removed by washing.

July 3—Seven cm. above the incision the sound feels a concretion in the hepatic duct.

July 4—Two concretions of the size of peas taken out.

July 5—Another stone removed.

July 8—In the depth of the hepatic duct another stone.

July 10—Stony particles flow out of the hepatic duct.

July 12—No more stones discharged.

September 6—Patient leaves hospital cured.

Case XV.[37]—D. B., fifty-seven years old. 15 years before operation, colic and slight icterus. Two years before operation severe colic, fever and chills. Directly before operation, quiescent.

Operation disclosed four fair sized stones in the common duct. In after-treatment 18 stones and many fragments were discharged through the drainage tube, during more than two months.

The following cases, with autopsy notes, as will be seen, corroborate the above interpretation of the preceding cases as well as my observation based on my own cases.

Case XVI.[38]—During operation on patient, who had been sick for three months with symptoms of cholangitis, a stone was found high up in the hepaticus. After removing it, bile flowed freely. Hepaticus drained seven days after operation. Three stones were discharged. On the eighth day, more stones were discharged from hepaticus and still more felt in depths. Patient died of pneumonia, and autopsy showed in the dilated intrahepatic ducts of second and third degrees more than twelve stones, the size of cherry pits.

Case XVII.[39]—Cholelithiasis gave symptoms three years before operation. Six months previous to operation colic, icterus, peritonitic irritation. Then improved, but four months before operation patient became sick again. At operation cholangitis and stone in choledochus. Also stones in gall-bladder. Death ten days after operation. Autopsy showed 20 small stones in left hepaticus and branches. In the branches of the right hepaticus there were 12 small stones as large as cherry pits. Ducts contained mucus and pus.

In these cases definite signs of cholangitis were present, before or during the operation, and here again we see the common cause of intrahepatic stone formation, a secondary cholangitis following an obstruction of the choledochus by stone. In one of these cases (Case XVI), the intrahepatic stones formed within three months, agreeing with my above post-mortem results. Whereas in one of my cases the stone was small four to five weeks after the onset of cholangitis and obstruction, in another case of my series, and in one of Kehr's cases, autopsy revealed stones the size of cherry pits three months after the commencement of the trouble.

(To be continued.)

THE VALUE OF A KNOWLEDGE OF ABNORMAL MOBILITY OF THE IRIS AS AN AID IN DIAGNOSING DISEASES OF THE NERVOUS SYSTEM.[1][2]

BY D. KERFOOT SHUTE, M.D.,

OF WASHINGTON, D. C.

SWANZY, a distinguished oculist and brilliant writer, says that the condition of the pupils, whether dilated, contracted or normal, is of very slight significance or value in the diagnosis either of the kind or the position of any intra-cranial lesion. And he goes on to say that slight in value as is the state of the pupils in cerebral cases, there is probably no symptom which receives more attention from the clinician in his note-taking. It has seemed to me that the oculist and the general practitioner alike could only draw the most misleading inferences from such an avowal. In consequence, I have taken great pains and labor to review a very extensive field of literature both in ophthalmology, and in nervous and mental diseases, in order to confirm or modify my very different conception of the value of a knowledge of abnormal pupillary actions.

In order to appreciate the significance of abnormal mobility of the iris in diseases of the nervous system, it is essential that we should thoroughly understand the anatomical basis for normal pupillary activity, and the appearance of the normal pupil. We should also have a knowledge of the variations of the pupil that are independent of diseases of the brain and spinal cord.

According to Woinow the diameter of the pupil varies, even when the accommodation is at rest, from 2.44 to 5.82 mm., the average diameter being about 4.14 mm. The size of the normal pupil, although determined mostly by the amount of illumination to which it is exposed, varies widely as to its condition of contraction and dilatation, according to the resultant of the many stimuli which react upon it directly or indirectly. In recording the size of the pupil or variations in

1 Read before the Medical Society of the District of Columbia April 6, 1904.

2 Received for publication April 19, 1904.

its diameter, pupillometers should be employed. Randall's modification of Follin's instrument is one of the best practical pupillometers and consists of a scale of circles. It is held close to the eye under observation and rotated until that circle is found which most nearly matches the pupil in size, and the diameter in millimeters then noted. This method of exactly ascertaining the diameter of the pupil under observation is much more useful than such loose statements as "medium-sized pupil" or "pupils dilated," etc.

The size of the pupil is larger in dark eyes than in blue ones; in myopia it is greater than in emmetropia and is more sluggish in response to the various stimuli. There is an associated condition of atrophy of the ciliary muscle. In hypermetropia the pupil is smaller than in emmetropia and acts more eneregtically to stimulation, and there is an accompanying hypertrophy of the muscle of accommodation. Between the twentieth and fortieth years the variations in the size of the normal pupil in the different types of refraction become less pronounced, while after the fortieth year the differences are scarcely appreciable. With advancing years the pupil normally becomes small in size. The small pupil of elderly people is due not only to sclerosis of the walls of the vessels and rigidity of the stroma of the iris, but also to a diminution of the activity of the sympathetic nerve. In the vast majority of cases in normal eyes the pupils are equal not only when both eyes are exposed to light or shaded, but also when one is shaded.

Where there is inequality of the pupils (anisocoria) the more sluggish or immobile pupil is the pathological one. Unequal pupils occur where one eye is blind, or where the character of the refraction in the two eyes is very different, in traumatism, dental caries, in paretic dementia, locomotor ataxia, insular sclerosis, migraine, and in focal disease of the brain.

Bilateral dilatation of the pupils may occur in cases where there is a deficient blood-supply to the brain centers or where there is diminution of blood in the vessels of the iris, as in anemia, syncope, nausea, shock, aortic regurgitation, trance, melancholia, the coma following an epileptic convulsion, and in depressed nervous tone. It occurs in fevers with active delirium; also in typhoid fever. There is a slight dilatation of the pupils at every ordinary inspiration depending on variations of the blood pressure.

Bilateral contraction of the pupil occurs in conditions producing congestion of the iris, as in plethora, typhus fever, mitral insufficiency and other diseases leading to venous congestion, and in pulmonary congestion. At every pulse beat there is a tendency to myosis through systolic filling of the arteries; bilateral contraction also occurs in diminished intra-ocular pressure (*e.g.*, paracentesis corneæ). During forced expiration two factors are at play in affecting the pupil: if the greater factor is the retention of carbon dioxide the pupil will be dilated by stimulation of the pupil-dilating center; if congestion of the head, and therefore of the iris, predominates, there will be contraction of the pupil.

The anatomy at the bottom of a simple involuntary response of the pupil to the direct and indirect light stimulus is as follows: first occur the rods and cones of the neuro-epithelium of the retina, then the bipolar cells, and then the neurons whose cell-bodies constitute the ganglionic layer of the retina. These cell-bodies send out axons which collectively constitute the bulk of the optic nerve; thence in sequence they form the optic chiasma and take part in the formation of both optic tracts. From each tract the pupillary fibers, as distinguished from the visual fibers, proceed through the superior brachium to the superior quadrigeminal body or colliculus of the corresponding side and terminate in arborizations around other cell-bodies located in these structures. The pathway extending from the retina to the superior colliculus on either side constitutes the afferent or centripetal one.

The cell-bodies located in either colliculus send out axons which descend and arborize around the cell-bodies of the oculomotor nucleus in the floor of the Sylvian aqueduct on the corresponding side of the median line. These neurons, extending between the superior colliculus of one side and the oculomotor nucleus of the same side, constitute the association pathway, or Meynert's fibers.

The oculomotor nucleus is highly specialized and differentiated into several nests of cells or subnuclei, such as those for accommodation, for pupil contraction, and for convergence. The axons of the cell-bodies situated in these subnuclei pass along the third nerve and constitute the efferent or centrifugal portion of the reflex arc.

It is through the pupillary fibers of the optic nerve on each side decussating partially and going through both optic tracts that each retina is brought into relation with both oculomotor nuclei, so that the light impinging on one retina can stimulate both pupil-contracting centers and cause both pupils to contract. If the light stimulus is applied to one retina, say the right one, and the right pupil contracts, we obtain the *direct* light reflex, the left pupil contracting under the same circumstances constitutes normally the *indirect* or consensual light reflex.

Another important mechanism by which the consensual light reflex is possible is due to the connection of the two pupil-contracting centers by commissural fibers.

Those efferent fibers destined to control the convergence of the visual axes in binocular vision go directly to the internal rectus muscles. Those that are to control the contraction of the pupil through the sphincter iridis and the accommodation of the eyes for points at varying distances through the ciliary muscles, pass to the ciliary ganglion and arborize around the cell-bodies there located. The axons of these cell bodies thence pass by way of the short ciliary nerves to the sphincter iridis and ciliary muscles.

The centrifugal pathway for reflex dilatation

of the pupil starts at the pupil-dilating center in the fore part of the floor of the Sylvian passage and is probably situated a little external to the oculomotor center. The cell bodies of this center send out axons that pass downward toward the ciliospinal center situated in the lower cervical and upper dorsal part of the spinal cord.

It is probable that a series of related neurons intervene between the pupil-dilating center in the crus cerebri and the pupil-dilating center in the cord, called the ciliospinal center, the last of the series arborizing around the cell-bodies in the ciliospinal center. From this latter center the cell-bodies send out axons that traverse the anterior roots of the first and second thoracic nerves, and their rami communicates, thus reaching the first thoracic ganglion and traveling thence along the cervical sympathetic to the superior cervical ganglion, where they arborize around the cell-bodies contained therein. These cell-bodies send out axons that traverse the cavernous plexus and the ganglion of Gasser (without arborizing in the latter) to reach the ophthalmic division of the fifth nerve and its nasal branch; thence they proceed by way of the long ciliary nerves to the dilator pupillæ. This complicated but well-defined route constitutes the centrifugal pathway for pupil-dilating stimuli.

One of the many centripetal pathways concerned in producing reflex dilatation of the pupil can be illustrated by studying the skin-reflex. If the skin of the neck be pinched, or better, stimulated with a faradic brush, the sensory impulse travels from the nerves of the skin through the posterior roots of the cervical spinal nerves directly, and indirectly by relays of neurons, to the ciliospinal center. The axons of this centripetal pathway that reach the ciliospinal center arborize around the cell-bodies contained therein and start impulses that traverse the centrifugal path, already described, to the dilator pupillæ muscle. Another centripetal pathway is from the cerebral cortex through the corona radiata, internal capsule and crus cerebri to the pupil-dilating center in the floor of the Sylvian passage and thence to the ciliospinal center. This latter is the route taken by the psychic impulses that dilate the pupil, as fear, anger, etc.

The centripetal pathways for dilatation of the pupil are as innumerable as are the pathways for all sensations except those of illumination. In health the reflex contraction of the pupil is invariably accomplished by the light stimulus or the convergence stimulus reacting upon the pupil-contracting center. Every other sensory and psychic stimulus reacts to a greater or less degree upon the pupil-dilating center, tending to stimulate the dilator pupillæ muscle.

The normal medium dilatation of the pupil is dependent mainly upon the presence of stimuli of medium intensity. In a person who is asleep or under complete anesthesia, and in whom therefore the psychic and all other stimuli are at their lowest intensity, the pupils are contracted.

Women, since they are of a more sensitive organization, have larger pupils than men. Nervous, sensitive people, have larger pupils than dull, phlegmatic persons of the same sex.

The reflex contracting and dilating movements of the pupil are altogether involuntary. If both the contracting and dilating mechanisms are stimulated simultaneously the pupil contracts.

But there are movements of the pupil which, though not immediately caused by efferent or afferent stimuli, are indirectly produced through correlation with the voluntary conjugate movements of the eyes from parallelism to convergence, or the reverse, in binocular vision. The centrifugal pathway for voluntary convergence of the visual axes in the horizontal plans starts from the cortical center for convergence, which corresponds with the macular center for convergence, in the middle of the calcarine fissure of the occipital lobe. The cell-bodies located in this region send out axons that traverse the optic radiations to reach the retrolenticular part of the internal capsule and thence proceed through the crus cerebri to the nucleus of the oculomotor nerve, arborizing around the cell-bodies of the convergence nucleus contained therein. There is such an intimate relation, through association fibers, between the single, medianly situated, convergence nucleus in the floor of the Sylvian passage and the accommodation and pupil-contracting centers on each side, that a stimulation of the convergence center effects simultaneously a stimulation of the ciliary and sphincter iridis muscles on both sides. Hence convergence of the visual axes normally causes a contraction of both pupils and constitutes what is known as the convergence stimulus of the pupils; a return of the visual axes to parallelism producing dilatation of the pupil.

While there is only one centrifugal pathway along which an impulse travels from the cortical center for convergence to the corresponding center in the mesencephalon, there are many pathways for afferent or centripetal impulses to reach the cortical center for convergence. If we take into consideration all the sense perceptions, all the associations of ideas, all the activities of memory, imagination, and the emotions, the resultant of which psychic processes constitutes the basis for volition, we may say that the afferent or centripetal pathways for influencing the voluntary movements of convergence and the correlated movements of contraction of the pupil are innumerable and vary immensely in their directness or indirectness and therefore in their complexity. But the principles underlying all these activities are few in number and easily comprehended. For instance, the light stimulus, falling on an excentric portion of the retina (a portion other than the macula lutea) passes along the optic nerve, chiasma, and optic tracts to the lateral geniculate bodies. Here the axons of the visual cell-bodies located in the ganglionic layer of the retina arborize around other cell-bodies located in these lateral geniculate bodies. Axons go out from these cell-bodies along the optic radiation and arborize around cell-bodies located in the corresponding

eccentric portion of the cuneus. Then associating neurons constitute the last relay of neurons in the afferent pathway by which the light stimulus is transmitted to the cortical (macular) convergence center, and cause the eyes to converge to the luminous point, through volition (and also frequently involuntarily). Of course involuntary reflex convergence, and the accompanying myosis, can be induced by stimulation of the convergence center by other afferent pathways.

Another complex afferent pathway is that by which a sound causes voluntary or involuntary movements of the head (and body at times) and convergence of the eyes toward the source or direction of the sound.

In *disease* the dilatation or the contraction of the pupil can be either irritative or paralytic, or both. *Paralytic mydriasis* is produced by an inhibiting disease, either of the pupil-contracting center, or of the fibers that pass along the third nerve to the sphincter iridis; it may also be due to disease of the centripetal pathway between the retina and the oculomotor nucleus. The pupil is moderately dilated, reacting only slightly to myotics, but dilating greatly under mydriatics. If the lesion be located between the pupil-contracting center and the sphincter iridis there can be neither direct nor consensual light reflex. Should the disease lie in the centripetal path between the retina and the pupil-contracting center the pupil can react to convergence and to the consensual light reflex, but not to the direct light stimulus. *Spastic mydriasis* is caused by an irritation of either the pupil-dilating center or the pupil-dilating fibers going to the dilator pupillæ muscle. In this form of mydriasis there is moderate dilatation of the pupil, and it does not dilate further in response to sensory stimuli. Myotics affect the pupil but slightly, while mydriatics dilate it to the maximum. The pupil contracts only moderately to the convergence and light stimuli.

While either form of mydriasis occurring separately evokes only moderate dilatation, the two occurring in conjunction would develop a maximum dilatation. *Paralytic myosis* is due to an inhibiting lesion of the pupil-dilating center in the mesencephalon or spinal cord or of the pupil-dilating fibers.

In this myosis the contraction is slight and the pupil is little affected by mydriatics, while myotics have a maximum effect. *Spastic myosis* is caused by an irritation of the pupil-contracting center or of the pupil-contracting fibers. The pupil is moderately contracted and reacts very slightly to reflex stimuli; but it is very responsive to myotics and mydriatics, these drugs effecting contraction and dilatation *ad maximum*. While in either paralytic or spastic myosis occurring separately the contraction is moderate, the two in conjunction would develop a contraction *ad maximum*.

A disease of the pupil-dilating center or its centrifugal fibers will induce either spastic mydriasis or paralytic myosis according to whether the lesion is in its early and stimulating stage, or whether it has advanced to its late and inhibiting phase. For instance, the early stages of diseases of the spinal cord in the cervical region will develop spastic mydriasis, as spinal hyperemia, meningitis, myelitis, and neoplasms: this spastic mydriasis is also caused by the pressure of enlarged lymphatic glands on the cervical portion of the sympathetic nerve, also by an aneurism of the arch of the aorta, or of the brachio-cephalic or common-carotid arteries. The later inhibiting stages of all these lesions would induce paralytic myosis. Traumatism of the cervical portion of the cord or sympathetic nerve would cause paralytic myosis. The toxin of locomotor ataxia frequently develops an early spastic mydriasis and a later paralytic (so-called spinal) myosis. This type of myosis is also an important symptom in the paralytic pseudo-dementia of syphilitic origin, and in paralytic dementia. It occurs also in insular sclerosis, in some forms of multiple neuritis, and in bulbar palsy when complicated with progressive muscular atrophy. The amblyopia of chronic alcoholism is frequently accompanied by paralytic myosis due to fatty degeneration in the medulla oblongata.

The value of a knowledge of pupillary abnormalities is well shown in the case of paralytic myosis. The small pupil in this condition is usually associated with retraction of the ball of the eye into the orbit and narrowing of the palpebral fissure and is most frequently observed in aneurism of the thoracic aorta or other mediastinal tumor; in chronic inflammations of the cervical portion of the cord; and in locomotor ataxia. In these cases a general inspection of the body will often enable the physician to make a diagnosis instantly. If the lesion be an aneurism some pulsation of the upper part of the chest would be observed; in diseases of the cervical cord, muscular atrophy of the upper limbs would be noticed and the position of the hands and the spastic attitude of the feet would be conspicuous; while in locomotor ataxia all the signs mentioned above would be lacking and both pupils would be small and inactive to light.

Spastic mydriasis also occurs in irritation of the sensory nerves of the intestines by worms or intestinal tumors: in the spinal irritation of people suffering with anemia after severe illness; in acute mania and melancholia; in paralytic dementia when it is often associated with paralytic myosis in the other eye, and in hunger. While mydriasis in spinal diseases indicates an irritative process, in cerebral lesions it points to an extensive inhibiting disease of the brain. Diseases of the pupil-contracting center, or its efferent fibers in the third cranial nerve, will cause either spastic myosis or paralytic mydriasis, according to the irritating or depressing nature of the lesion. Spastic or irritative myosis is symptomatic of early stages of inflammatory diseases of the brain and its meninges; it is present in the early stages of epileptic and hysterical attacks; in the early stages of intracranial tumors involving the third nerve. If, during the course of tuberculous, simple or cerebro-

spinal meningitis, or other inflammatory affections of the brain, mydriasis replaces the medium myosis the prognosis becomes graver. It points to paralysis of the third nerve and indicates the stage of depression. Spastic myosis occurs in engravers and watchmakers in consequence of the protracted stimulation of the convergence and accommodation centers; also in those having tobacco amblyopia due to the excessive stimulation of the myotic center by the nicotine.

In apoplexy due to hemorrhage there is at first spastic myosis (or the pupils may be unequal) and the light reflex is lost, whereas in thrombosis and embolism the pupils are not myotic and they react to light and are equal. When spastic myosis occurs in abscess of the brain the myosis is at first on the same side as the lesion. Spastic myosis occurs when the cerebellum is invaded by small hemorrhages; also as a reflex action in many diseases of the eye involving irritation of the trifacial nerve; and in pressure on the pons. The lesion of the pons in which bilateral myosis is most frequently observed is hemorrhage into this structure. When a patient is in profound coma and has great contraction of the pupils,—opium poisoning being excluded,—a hemorrhage into the pons varolii should always be suspected. Occasionally the double myosis is noted in meningeal hemorrhages that occur through the corpus stratium into the lateral ventricle. Frequently, in pontine apoplexy, the pupils, instead of being contracted, are normal. The collateral or accompanying symptoms are required to locate and define the nature of the lesion.

Paralytic mydriasis is caused by diseases of the orbit and intra-ocular growths that produce pressure upon the ciliary nerves; in glaucoma for the same reason (although cloudiness of the media and diminution of illumination also encourages the mydriasis); in lesions of the brain causing increased intracranial pressure, such as hemorrhage, tumors, and large abscesses; in hemorrhage into the crus cerebri or the centrum ovale; in cerebral softening; and in acute dementia with edema of the cortex. In the late stages of paralytic dementia irritative myosis gives place to paralytic mydriasis. When first one eye and then the other is affected by transient mydriasis the symptom is to be regarded as a prodrome of insanity. Optic atrophy, by preventing the conduction of the light stimulus, induces paralytic mydriasis, but does not prevent reflex contraction of the pupil in response to the convergence stimulus.

Another anomaly of the pupil is hippus. *Hippus* may be defined as a normal clonic rhythmical spasm of the sphincter iridis. With a given fixation and illumination there is a rhythmical dilation and contraction of the pupil. Even when the pupil seems perfectly quiet its inspection with the corneal microscope will reveal that there are minute and irregular variations in its size that are perpetually taking place in response to the ever-changing psychic and sensory impulses that are playing upon the pupil-dilating center. This minute hippus has been aptly designated the "unrest of the pupil." Hippus, when pathological, is usually associated with nystagmus. The latter symptom is a clonic rhythmical spasm of the muscles concerned in producing conjugate lateral and other movements of the eyes. Both abnormal hippus and nystagmus are very important symptoms in the diagnosis of insular sclerosis. Abnormal or exaggerated hippus occurs in mania and other psychical disturbances; in hysteria, epilepsy and meningitis; it is not only comparatively frequent in insular sclerosis but it also, in two recorded cases, was the only brain symptom noted.

As nuclear palsy of the convergence center in the floor of the Sylvian passage is relatively frequent in this sclerosis the pupillary symptoms pertaining to that palsy are often noted. In neurasthenia and in cases of secondary spasms and tremor following attacks of apoplexy, there is a very noticeable increase in the oscillations of the puplis. Through irritation of the first thoracic ganglion by tuberculous glands a transient, rapid, and unsymmetrical dilation of the pupils may be observed in a considerable number of cases of tuberculosis. Buzzard taught that of all the organic diseases of the nervous system, insular sclerosis in its early stages is most commonly mistaken for hysteria. Since a series of rapid contractions and dilations of the pupil on sudden exposure to light occurs in both of these diseases, the associated symptoms of the hippus are necessary to differentiate the diseases, particularly the associated eye-symptom known as nystagmus that occurs in the sclerosis.

When a pupil reacts slowly to light it indicates that chronic degenerative changes are taking place in the nervous system. *Basal lesions* of the third nerve are common factors in producing pupillary disturbances,—usually paralytic mydriasis. The most common cause is the gummatous exudate of syphilis. In basal lesions there is very generally an involvement of several nerves without reference to symmetry, and this fact constitutes the chief diagnostic feature of these lesions. A crossed paralysis of the third nerve due to basal lesions cannot always be distinguished from that induced by pontine disease. Usually in the former the symptoms appear gradually and in sequence; in the latter simultaneously and suddenly.

Swanzy believes that an indolent and chronic form of meningitis due to rheumatism, even when no other signs of rheumatism are present, is often a cause of basal paralysis of the third nerve. There may be immobility of the pupil, coming and going from day to day. In the investigation of basal lesions it is well to remember that tumors of the frontal lobe of the cerebrum tend to grow toward the base of the brain and there directly involve the cranial nerves. Also basal paralysis occurs as a distant or pressure symptom of tumors of the cerebellum and cerebral hemispheres.

A neoplasm occupying the cavernous sinus, a rupture of the cavernous artery in the cavernous sinus, an aneurism of the cavernous artery or of the intracranial portion of the ophthalmic artery,

and thrombosis of the cavernous sinus, may all involve the third nerve, either by direct pressure or indirectly by pressure of the distended ophthalmic vein. Hence, in these affections pupillary symptoms may be prominent. According to the amount of irritation or depression of the third nerve, there would be irritative myosis or paralytic mydriasis.

Fascicular or crossed paralysis of the third nerve is another important condition causing abnormal pupillary phenomena. Since the superior peduncle of the cerebellum, like the third nerve, is intimately related to the red nucleus in the tegmentum, vertigo is a common symptom in fascicular paralysis of the third nerve.

Nuclear disease of the oculomotor nerve is a common cause of symmetrical mydriasis and may be developed by many causes. It may complicate bulbar paralysis, progressive muscular atrophy, paralytic dementia, insular sclerosis, locomotor ataxia, multiple neuritis, exophthalmic goiter, and occurs as a sequel of diphtheria, grip, diabetes, and purpura; it follows injuries to the head unaccompanied, as well as accompanied, by fracture. The most common causes of primary cases of this disease are alcoholism and syphilis. Other causes are poisoning by carbonic oxide, nicotine, ptomains, sulphuric acid, lead, and exposure to cold, also congenital predisposition, where it occurs in young children. According to Swanzy, chronic alcoholism is the factor in developing what he calls sudden or peracute nuclear ocular palsy. Paralysis of the power of convergence due to nuclear disease of the convergence center in the floor of the Sylvian aqueduct gives well-defined pupillary symptoms. In this affection the power to fix both visual axes upon the same point is lost, while the eyes separately or together can move to either side. In other words the nucleus of the sixth nerve on either side can be stimulated and evoke conjugate lateral motions and each internal rectus can respond to a stimulus from its own special nucleus. In this focal disease of the brain the light reflex is intact, and the pupil is not dilated, but the reflex contraction of the pupil does not occur on attempting to converge the eyes,—the convergence stimulus is abolished. A greater or less impairment of accommodation is a concomitant of these conditions. This nuclear paralysis must be carefully distinguished from the impairment of convergence that is common in exophthalmic goiter and which is due to mechanical causes; and also from insufficiency of the internal recti that may be associated with myopia. Berry records a case of spasm of convergence due to hysteria. Although he does not mention it, I presume the condition was accompanied by irritative myosis.

Thrombosis of one cavernous sinus may spread through the circular sinus to the opposite cavernous sinus, causing total immobility first of one eyeball and then the other. This condition would be differentiated from nuclear ophthalmoplegia by the presence of edema of the lids and chemosis, optic neuritis, exophthalmos, pain, and finally loss of sensation. In addition to these local symptom, there would be chills, fever, etc. The symptoms diagnostic of nuclear palsy of the ocular muscles are their bilateral and often symmetrical occurrence, and also the fact that commonly either the intrinsic or the extrinsic muscles alone are paralyzed, also the frequent immunity of the levator palpebræ.

Tumors of the pineal gland and other tumors in the region of the quadrigeminal bodies by compressing the nuclei in the floor of the aqueduct of Sylvius furnish an important localizing distant symptom because impairment of the muscles of the eye very similar to those of nuclear ocular palsy (ophthalmoplegia) will be present. This ocular palsy is commonly associated with cerebral ataxia. A tumor of the median region of the cerebellum, as the vermis, has engendered the same group of symptoms. Pupillary disturbance is a frequent concomitant of the other eye symptoms.

Wernicke's Pupil Symptom.—A lesion of the visual path between the optic chiasma and the cortical center for vision will cause the symptom known as homonymous hemianopsia. The presence of Wernicke's pupil-symptom is diagnostic in enabling us to locate the lesion in the optic tract. This symptom is difficult to evoke. The attempt to produce it should be made in a dark room with the aid of an assistant. The source of illumination can be a gas jet of moderate brightness and should be situated behind the patient, and the latter directed to look into the distance. The pupil should then be moderately illuminated by the assistant reflecting light into it with a plane ophthalmoscopic mirror while the examiner directs from the concave mirror of his ophthalmoscope a narrow beam of light upon different portions of the retina. If the light is reflected upon the hemiopic portion of the retina to the exclusion of the remaining portion, either there will be no light-reflex of the pupil or, which is more usual, the pupillary response will be much more sluggish than when the light is reflected upon the normal half of the retina. The lack of promptness of the pupillary reaction, rather than its entire absence, in the test for hemiopia, is due to the fact that it is impossible to prevent some of the light from reaching the normal side of the retina. The pupillary movements may be quite delicate in this test, and therefore the pupil should be very carefully observed.

A simpler and much more accurate test, and one that can be applied without the aid of an assistant is to use the instrument devised by Von Fragstein and Kempner instead of the concave mirror for sending a very small beam of light upon various parts of the retina.

Great care should be exercised in throwing the beam of light into the eye so as to be sure that its angle of incidence as well as its intensity shall be as nearly as possible the same on each side of the retina. This is important because a variation in the angle of incidence of the beam of light sent through the pupil of a perfectly normal eye on

one side and then on the other will cause a decided difference in the rapidity and promptness of the pupil reflex. It should be borne in mind that occasionally in the same patient Wernicke's pupil-symptom may be present at one observation and then on a subsequent day be absent. This is to be explained by the presumption that the pupillary nerves in the optic tract are damaged but not destroyed, so that they may be more responsive to stimuli on some days than on others. Again in lesions of the optic tract hemianopsia may be present while Wernicke's pupil-symptom is altogether absent, owing probably to the greater vulnerability of the visual nerves than the pupillary ones.

Wernicke reports a case of brachial monoplegia, associated with homonymous hemianopsia which resulted from a stab in the head. The detection of his pupil-symptom (the hemianopic pupillary inactivity) led him to make the correct diagnosis of injury of the optic tract and of the closely related crus cerebri. Henschen reported observations on a patient who presented fleeting conditions of hemianopsia and Wernicke's pupil-symptom. The lesion was a tumor of the dura mater pressing against the brain in the region of the fissure of Sylvius, and evoking the symptoms by disturbance of the blood-circulation.

A case published by Leydon shows that tumors of the lenticular nucleus, the optic thalamus, crus cerebri, and the temporal lobe of the cerebrum may encroach upon the optic tract and cause homonymous hemianopsia and the hemiopic pupil. In this case of Leyden's there were left hemianopsia and Wernicke's pupil-symptom, associated with left hemiplegia, left ptosis and facial paralysis, and finally, conjugate deviation of the eyes to the right. The last symptom indicated a lesion in the right cerebral hemisphere, while all of the other symptoms, collectively, suggested a lesion of the right crus cerebri and optic tract. At the autopsy a tumor was found that involved the crus cerebri, optic tract and lenticular nucleus on the right side of the brain.

Syphilitic meningitis and gummata, and tubercles are the most frequent lesions of the optic tract. Hemorrhages and softening are uncommon.

There are no pupillary symptoms that enable us to differentiate between the hemianopsia due to lesion of the optic radiations and that due to disease of the cortical visual centers. While the association of Wernicke's symptom with homonymous hemianopsia would indicate a lesion of the optic tract, its conjunction with bitemporal hemianopsia would indicate a disease of the middle segment of the chiasma involving the decussating fibers. If the hemianopsia were unilateral, and not dependent on disease of the retina, it would suggest an injury to one optic nerve. The hemianopic pupil is a rare symptom in infantile paralysis. In hydrocephalus, owing to the pressure by the floor of the distended third ventricle on the optic chiasma, there is great liability to bitemporal hemianopsia and the hemiopic pupil. It is because of the great difficulty in eliciting Wernicke's symptom that it was so long overlooked. It was not observed until several years after it was announced by Wernicke as one that should, on theoretical grounds, be capable of detection.

Pupillary symptoms in *epilepsy* are quite important at certain times. During an epileptic seizure the pupils are quite variable. Usually at the commencement of the attack there is spasmodic myosis, or the pupils are normal but they undergo paralytic mydriasis during the phase of tonic spasm and so continue until the return of consciousness. The convulsions of meningo-encephalitis are associated on the other hand with a contracted pupil. The fact that the light-reflex is retained during a hysterical convulsion but is lost during an epileptic spasm is of value in differentiating one form of convulsion from the other. Another important aid in distinguishing a true epileptic convulsion from that of hysteria or of a malingerer is the presence in the former of hippus or rapid alterations of the pupillary diameter.

In *locomotor ataxia* the pupil may be normal or even dilated, but commonly it is contracted. Frequently the contraction is so extreme as to constitute the condition known as "pin-hole" pupil,—a state due, not to irritative myosis, but to a secondary contracture of the sphincter iridis due to paralysis of the dilator pupillæ. The abnormal condition of the iris may be due to a lesion, either of the brain or the spinal cord. In the former case the seat of the disease is in the pupil-dilating center of the floor of the aqueduct of Sylvius. In the latter case the lesion is located in the upper dorsal and the lower cervical portion of the cord. In either instance the myosis of pupil is of the paralytic type. In those cases, usually early, of locomotor ataxia in which Meynert's fibers are not involved, there is only a medium myosis and the pupil reacts to the light reflex as well as to convergence; but later in the disease when the fibers of Mynert are involved, the pupil, while responding to the convergence stimulus, does not do so to light or, at least, only very slightly. This constitutes the very valuable clinical symptom known as the Argyll-Robertson pupil. If Meynert's fibers are uninvolved the pupil reacts to light as well as to convergence, even when it exhibits the extreme myosis known as the "pin-hole" pupil. In testing for the presence of the Argyll-Robertson pupil care must be exercised not to confuse unilateral reflex blindness with unilateral reflex iridoplegia, for in both cases there is absence of direct light reflex on the diseased side, but response to the convergence stimulus. In the former case there is a lesion in the centripetal pupil-contracting fibers either in the retina, optic nerve, optic tract, or superior brachium. In the unilateral iridoplegia the lesion is in the sphincter iridis subnucleus of the oculomotor nucleus.

The Argyll-Robertson pupil occurs not only in locomotor ataxia, but also in paralytic dementia, atrophy or softening of the brain, insular sclerosis, in tumors of the basal ganglia adjacent to the third ventricle, in hydrocephalus, syphilis of the

brain, and as a congenital defect. If there should be a response of the pupil to the direct light stimulus, but not to the convergence stimulus, we would have the reverse of the Argyll-Robertson pupil, indicating a lesion of a particular part of the oculomotor nucleus. In a considerable number of the cases an eliptical pupil has been noted with the long axis in the vertical meridian. Both in the late and the early stages, in many cases, the pupils present inequalities of size.

The commonly accepted theory of the Argyll-Robertson pupil is as follows: it is a lesion of Meynert's fibers, that is, of the fibers extending from the superior quadrigeminal bodies to the nuclei of the third nerves in the floor of the Sylvian aqueduct. This explanation is sufficient in the vast majority of cases of locomotor ataxia because the Argyll-Robertson symptom is most frequently binocular. But in those cases where the symptom is monocular the current explanation is inadequate. It can be readily understood that if only the fibers of Meynert on one side be diseased, the others being normal, that the direct light-reflex may be elicited on the normal side and the indirect or consensual light-reflex may be developed through the internuclear fibers that connect the nucleus of the sphincter iridis of one side with that of the other. In consequence of these facts Bevan Lewis, Heddæus and Jessop teach that the Argyll-Robertson pupil is a nuclear disease, that is a disease of the nucleus of the sphincter iridis nerve. Heddæus believed that there is no direct communcation between the nucleus of the sphincter iridis nerve and that of the ciliary muscle nerve, and that the branch of the third nerve going to the ciliary muscle and the sphincter iridis, contains two independent roots, one from the nucleus of accommodation and the other from the nucleus of the sphincter iridis muscle, so that the disease causing loss of the direct light-reflex could be fascicular as well as nuclear, for destruction of the nerve-root springing from the sphincter iridis nucleus would give loss to the pupil reflex from direct light as well as destruction of the sphincter iridis nucleus itself. Yet Swanzy points out that this theory is not tenable because myosis is a very frequent accompaniment of the Argyll-Robertson symptom. If the view of Heddæus were true the sphincter iridis would always be paralyzed in these cases and the unopposed dilator pupillæ, under the tonic influence of the sympathetic, would always dilate the pupil, thus giving mydriasis as the uniform symptom accompanying the Argyll-Robertson pupil, whereas myosis is the common symptom. In view of all the facts of the case Swanzy makes the observation, which is fully justified in my opinion, that there is much to be learned before an entirely satisfactory explanation of the occurrence of this valuable clinical symptom can be given. Peripheral neuritis is liable to be occasionally mistaken for locomotor ataxia, but the presence of the Argyll-Robertson pupil would readily exclude the former.

Pupillary Symptoms in Insanity.—Anomalies of the pupil are very frequent in the prodromal stages of mental diseases and are therefore of great clinical value. They may, in various cases, consist of irregularity of the shape of the pupils, inequality of the size, loss of the indirect or consensual reflex and of the direct light reflex, the presence of the Argyll-Robertson pupil, of mydriasis or myosis, the absence of the skin reflex, and the paradoxical pupil symptom. In acute curable dementia, or what Berkeley calls "states of mental stupor" the pupils are commonly dilated and react only slowly to convergence, to light, and to skin stimuli. In syphilitic insanity mydriasis and irregularities of the pupils are more usual than contraction. The various psychoses of old age manifest irregularities of the pupils, and present pupils that react slowly to convergence, skin or light reflexes. That organic lesions are present in both acute and chronic alcoholic insanities is evidenced not alone by the presence of tremor and occasional paresis of the facial nerve, but also by unequal or myotic pupils. While pupillary inequalities are quite common in the alcoholic insanities, the tardy reaction of the pupil to convergence and light is much less common than in paralytic dementia. In paranoia abnormalities of iris movement are infrequent, having been observed in about only one per cent. of the cases. And in this connection it is interesting to note that a number of cases of chronic progressive paranoia ultimately develop into paralytic dementia.

Pupillary Symptoms in Paralytic Dementia.—The most common condition of the pupil in this grave disease is marked contraction of the sphincter iridis due to paralysis of the dilator pupillæ through disease of the sympathetic nerve. In this condition the pupils are extremely small and do not expand when the eye is shaded, and they are uninfluenced by exposure to light. Sometimes, in the early stages, when so-called iridoplegia is commencing, the pupil is responsive to a beam of light concentrated upon it by focal illumination; but even then the mobility of the iris is quite limited in extent and presents the hippus or oscillatory movement with a tendency even to wide dilatation.

This dilatation under focal illumination constitutes the paradoxical pupil symptom. This paralytic myosis has sometimes been present for ten years before the complete development of the disease. Paralytic myosis, and therefore, reflex immobility of one pupil alone, is seldom permanently noted since the other soon becomes involved. In eliciting the symptom of reflex immobility, the convergence and therefore the accommodation reaction should be carefully eliminated. The examiner must also take the precaution to ascertain that the patient's eye is not immobile in consequence of the rigidity of sclerosis, or of atrophy of the iris, posterior synechiæ due to a mild or transient iritis, or a myotic drug, etc.

The pupillary symptom next in importance to paralytic myosis is the absence of the indirect or consensual light reaction. The consensual reflex is elicited as follows: both eyes are shaded with-

out touching the skin around either orbit, so as to avoid the liability of introducing the complicating sympathetic or skin-reflex of the pupil. Then one eye, say the left one, is suddenly uncovered when the right pupil will undergo a contraction with following wavy dilatation. Berkeley states that he has observed this consensual wavy dilatation of the pupil before the loss of the light reflex, and its appearance in conjunction with mental phenomena has always led him to make a provisional diagnosis of paralytic dementia.

Another pupillary symptom of much importance in general paresis is the absence of the skin-reflex. Bevan Lewis found that this reflex was present in only about 11 per cent. of his cases, whereas it was entirely absent in about 67 per cent. Associated with the pin-hole pupil in this disease is loss of the power of accommodation, especially in the later stages of the paresis. Rarely, in consequence of optic atrophy or other grave defect of vision, one or both pupils may be widely dilated. Gudden states that a little under five per cent. of his cases of paresis exhibited double mydriasis. In the early stages of paresis the ophthalmoscope will reveal that the fundus of each eye is normal. Swanzy states that in consequence of a number of cases that have come under his observation he has been led to think that the full value of the Argyll-Robertson pupil in relation to nervous diseases has not yet been fully appreciated. Dr. Branwell states that in the vast majority of instances in which he has observed the Argyll-Robertson pupil it has been associated either with locomotor ataxia or paralytic dementia.

Gowers has expressed the opinion that this pupillary symptom proves that a degenerative process is at work in the nervous system which raises a strong presumption that the process is of syphilitic origin. We know that the two most potent causes of locomotor ataxia are heredity and syphilis. We also know that these two etiological factors are by far the most frequent ones in paralytic dementia. While the majority of physicians look upon locomotor ataxia and paralytic dementia as having nothing in common, it seems to me that the facts related above and many others, justify the German and French physicians in regarding the two diseases as fundamentally alike, in spite of the fact that in tabes the spinal symptoms are quite constant, whereas in dementia paralytica they are of an ever shifting character. It has been observed that while there is a diminution in the intensity of the oscillations of the pupil (hippus) in locomotor ataxia, their rhythm is unchanged, in paralytic dementia the rhythm is lost. Yet in spite of these differences dementia paralytica has been called the half-brother of locomotor ataxia.

It should be borne in mind that paralytic dementia and *neurasthenia* have a large number of similar and misleading symptoms. In each heredity is important, and they belong especially to the middle period of life. In each a syphilitic history is very prominent, and sexual, alcoholic, and mental excesses are noted. Insomnia, headache, vertigo, irritability, indigestion, and inability to concentrate the mind are prominent symptoms.

A number of cases that have been diagnosed and treated as neurasthenia have ultimately turned out to be cases of paralytic dementia. In differentiating these two diseases the pupillary symptoms are of the utmost importance. In the eye, mental, and nerve clinic of the Charité in Bonn, Thompson found that of those patients who developed paralytic dementia or locomotor ataxia, 90 per cent. had reflex immobility of the pupil to light. Berkeley states that many of these patients went to the various clinics under the impression that they had neurasthenia, and he admonishes the physician to think twice before contenting himself with a diagnosis of neurasthenia in a man or woman who in middle life shows well defined reflex pupillary disturbances, for the prognosis of insanity is ominous. It would be extremely difficult to differentiate paralytic dementia from certain forms of chronic alcoholism were it not for the help of eye-symptoms. In both of these diseases along with the lowered intelligence, defects of speech and writing are noted, as also anomalies of sensation, tremors, and epileptiform seizures. Also in those patients who have peripheral neuritis the patellar reflex is abolished. But the presence of paralytic myosis or contraction of the pupil and other eye symptoms would point strongly to the presence of paralytic dementia. The prognosis in paralytic dementia is altogether bad. Even those cases which apparently recover for a time and are able to return to business for a year or two, show the lurking presence of the disease by the inactivity of the pupil, associated with slight tremors of the hands, and the abolished or increased knee-jerk.

Occasionally there is inequality of the pupils in encephalopathia saturnia; also at times in Morvan's disease or syringomyelia.

In Parkinson's disease of paralysis agitans the pupils are normal, the myosis that is noted being common in healthy elderly people.

In Landry's disease or acute ascending paralysis, although eye-symptoms are rare, there has been observed either a loss of the light reflex or a dilated pupil. In myotonia congenita or Thomsen's disease, and also in hereditary ataxia or Friedreich's disease, no pupillary symptoms have been observed.

A knowledge of the different phases of mobility of the iris in chloroform narcosis is of the utmost practical importance, and affords a brief but very instructive review, of the philosophy of pupillary changes. In the excitation stage of chloroform anesthesia the drug first dilates the pupil by stimulating the pupil-dilating center, thus inducing spastic mydriasis, then later the center is depressed, and still later, as the chloroform narcosis becomes more pronounced the pupil-dilating center is completely inhibited, so that wide dilatation gives place to medium contraction, through unopposed tonic activity of the oculomotor nucleus

and we have paralytic myosis. The narcosis becoming more pronounced the pupil-contracting center is stimulated and produces the "pin-hole" pupil or spastic myosis. As the patient is carried into the condition of profound surgical anesthesia there is a slight dilatation of the pupil due to commencing inhibition of the pupil-contracting center in the gray floor of the Sylvian passage. Should a marked dilatation of the pupil now occur, especially a sudden one, it is a danger signal and indicates that inhibition of the pupil-contracting center has been superseded by paralysis of this center, and admonishes us that the life of the patient is in grave jeopardy (paralytic mydriasis).

MEDICAL PROGRESS.

SURGERY.

Removal of the Semicircular Canals.—The excision of this portion of the ear for the treatment of unilateral aural vertigo is an operation attended by considerable risk, but capable of affording very great relief in certain chosen cases. Richard Lake (*Lancet,* June 4, 1904), cites the history of a woman, twenty-one years of age, who had suffered from aural vertigo complicated with vomiting for five years. Deafness and tinnitus were both gradually but certainly increasing. The use of suitable glasses made no difference whatsoever in the frequency of her attacks. She experienced no constant dread of falling in any particular direction. She had been given almost every conceivable drug for the relief of the condition, among others, hypodermic injections of pilocarpine, having been used to their full limit. An ordinary mastoid operation was first performed with the exception that the innermost portion of the posterior wall was not removed. The temporal opening being advanced forward, upward and backward The malleus and incus were removed, after which the upper and outer surfaces of the external semicircular canal were exposed. The superior canal was then brought into view and removed with a medium-sized burr. The posterior canal was then burred away entirely. The shock from this operation was very profound. For forty-eight hours the patient lay coiled up on the right side in the position commonly ascribed to patients suffering with cerebral irritation. The eyes were tightly closed, but the balls moved erratically. On the seventh day she sat up. On the tenth day she was able to take a few steps and in two weeks she could easily walk twenty yards. She could turn only toward the sound side. If she attempted to turn to the operated side she fell toward the sound. At the end of four weeks she was able to do everything without fear of falling. Since the fourth day there have been no movements of the eyes, abnormal in character. For the past three months there has been no return of the vertigo, and this may be looked upon as a great achievement, inasmuch as the patient was entirely incapacitated by her disease. It appears justifiable from the history of this case to believe that there are many which would respond to similar treatment in a similar gratifying manner, the important point being the question of indication for operation. The question for interference with the hearing is not a deterrent, because these patients apparently are not made much worse by operation, and, indeed, if they were, the relief would justify the entire destruction of the organ of hearing on one side. The operation itself is not difficult except when made so by anatomical anomalies and irregularities. Probably it is impossible to avoid entirely the evidences of cerebral irritation and the eye symptoms, although in the author's case it is believed that the use of Lister's strong solution was in part responsible for the phenomena described. He recommends, therefore, that when this operation is done, a mild antiseptic wash should be used, because it has been shown that chemical irritation of the parts produces more reaction than actual section.

Disinfection of the Skin.—Animated by the idea that the source of infection in operative wounds was to be found in the patient's skin as often as in the surgeon's hands, E. W. Siekemeier (*Archiv. f. klin. Chir.,* Vol. 73, No. 1) has made a series of experiments with this in mind. He recommends as the result of these observations that the patient be cleaned outside of the operating room and an abundance of flowing water be used. He found that after fifteen minutes of cleaning a large number of bacteria would be left on the skin, unless a brush were used. After the use of the latter a marked diminution in the number of bacteria was found. Tincture of green soap is a most valuable adjunct, but can be rendered much more effective if employed after one or more washings with ordinary soap.

Experimental Studies on Entero-anastomosis.—As the result of experiments made in the higher animals, T. Sato (*Archiv. f. klin. Chir.,* Vol. 73, No. 1) has found that if two sections of small intestine, or stomach and intestine, be held in apposition, with the outer layers removed so that the mucous surfaces are exposed, no communication between the lumena of the two will result, unless some destruction has taken place. The resistance of the mucosa is of such a high grade, that a mere exposure of a considerable segment, or the approximation of two such, never leads to perforation. In addition to producing apposition it is necessary to reduce the nutrition of the mucosa by chemical or thermic irritants, and thus to bring about a necrosis. For this purpose the author prefers the nitrate of silver stick to the actual cautery.

Modified Method of Stitching in Bassini's Operation.—It is well known that one of the most objectionable features attending this operation is the possibility of stitch infection in the lower tier of stitches. Robert Porges (*Zentralbl. f. Chirurgie,* May 28, 1904) states that while the usual period of convalescence from a non-infected operation may be conservatively placed at three weeks, the period is lengthened to from six to fourteen weeks if the sequel under consideration subvenes. He states that not only in his work, but in the work of some of the ablest operators in Vienna and other parts of Europe, so much attention has been bestowed upon this subject that he has developed a method of placing the deep stitches so that if infection occurs in them, immediate drainage may be had in a more convenient manner than as they are at present inserted. The operation is done exactly as Bassini does it until the beginning of the deep sutures, which unite the internal oblique to Poupart's ligament. These are inserted, but are not tied in the usual way, being made fast to a fine piece of silk, which is carried out through the wound together with the terminations of the deep stitch. The superficial suture is put in, in the form of a figure of eight, so as to include the external oblique and the skin. The article is well illustrated so that the method of introducing the stitches is easily understood. All the deep stitches, when applied after this method, lead to the outside, an obvious advantage in cases of infection. When the wound is closed, the figure-of-eight stitches appear at intervals, while the deep stitches are brought out through the wound, held by artery forceps. When it is desired to remove the stitches, these are opened and the fine silk, which was previously mentioned as being

brought to the surface, with the terminations of the deep stitches, is used as tractors. The author states that this method can be pursued without any considerable loss of time and that he has found it satisfactory in every detail.

Crepitus from the Scapula.—This interesting condition has been alluded to by few writers, and the case reported by AXMANN (*Deut. med. Woch.*, June 23, 1904) is therefore worthy of attention. His patient was a boy of eighteen in whom a loud crepitus gradually developed in the right shoulder, although the boy was otherwise in good health and had sustained no injury. On lifting the arm, the crackling sound could be heard for several yards. Nothing was heard on passive motion and muscular effort seemed necessary in order to elicit the noise. The X-rays failed to show any abnormalities. No symptoms were complained of. In Kuttner's report, 22 cases of this condition are mentioned, and the following are stated as etiological factors: Bony deformities in the scapula or thorax which are the result of tuberculosis or syphilis; ankylosis in the shoulder joint; paralysis with muscular atrophy; and abnormal diverticulae from the synovial membrane. In this case, however, none of these lesions could be demonstrated.

Determination of Renal Capability.—It is of prime importance that a careful examination of both kidneys be made before attempting a radical operation on one. J. W. CHURCHMAN (*Maryland Med. Jour.*, July, 1904) says the usual methods of urinary analyses, actinography and cystoscopy as well as subsequent exploration of the healthy kidney may give no clue as to changes in kidney tissue which might impair the working capacity of the organ. The usual urea tests are inaccurate for more than the urea is measured, but the great difficulty of accurate tests renders them useless clinically. Inferences regarding normal or subnormal functional capacity of the kidneys are not warranted from a single observation, since wide daily variations may occur in kidneys doing physiological work. Routine urea tests even when continued over relatively long periods are not precise since maintenance of nitrogen equilibrium does not necessarily speak against nitrogen retention, likewise a deficiency in nitrogen output does not of necessity mean retention of toxic products. The ordinary tests, however, should not be disregarded, as they have the clue-giving value of all rough methods. It is suggested that some substance be injected into the organism, easy of detection in the urine, and that the renal capacity be judged from the manner in which such a substance is excreted. Two such methods are described. The technic of the first consists in the subcutaneous injection of 5 m.g. of a solution composed of equal parts of phloridzin and sodium carbonate, the bladder having previously been emptied. In normal cases sugar appears in the urine in a half hour, the quantity being about 3 per cent. In general, disease is indicated by (1) absence of sugar after a reasonable interval; (2) delay in its appearance; (3) a small percentage of sugar. In the second method one c.c. of a sterile 1-20 solution of methyl blue is injected deeply into the buttocks, after emptying the bladder. The urine collected every half hour until the blue appears and then every half hour until it disappears. Normally the blue appears in the first hour and disappears in 36 to 48 hours. The time of appearance, intensity, duration and course (cyclic, polycyclic or intermittent) of elimination must be considered before a conclusion can be reached. By determining the freezing point of urine and comparing it with that of blood (cryoscopy), the molecular content of the urine may be estimated and an index of osmotic pressure given. A test tube containing the urine, a finely-graded thermometer and a stirring wire, is suspended in a freezing mixture. When the liquid freezes the latent heat given off causes a sudden rise of mercury, the freezing point is determined by the point from which the mercury rises. Urine normally freezes between -0.9° and -2°, that from healthy kidneys has a lower freezing point than that of diseased kidneys. Blood freezes normally at 0.56°, a lower freezing point means renal insufficiency. The practicable methods of determining renal capability are not accurate, but the accurate methods are as a rule not practicable. Of the methods comparatively simple in technic cryoscopy is recommended as giving best results, its chief advantage being that it gives an index of total waste products instead of that of a single constituent.

MEDICINE.

Pseudo-ascites After Chronic Enteritis.—L. TOBLER (*Deut. Arch. f. klin. Med.*, Vol. 80, Nos. 3 and 4) has noticed that children suffering from chronic enteritis are frequently brought to the physician for an increasing swelling of the abdomen. If these emaciated patients are examined all the physical signs of free fluid in the abdomen may be obtained, that is, the skin is tense and shiny, undulation is present and movable dulness may be elicited. The symptom-complex strongly suggests tuberculosus peritonitis, yet the areas of dulness are liable to vary from day to day. If such patients are operated on there is generally not a trace of fluid in the abdomen. The condition is due to a relaxation of the mesentery, so that the intestines, filled with fluid contents, will sink to the most dependent portions of the abdomen.

Painful Obesity.—Three new symptoms have been added by B. SCHWENKENBECHER (*Deut. Arch. f. klin. Med.*, Vol. 80, Nos. 3 and 4) to that peculiar condition known as adipositas dolorosa: general muscular weakness, physical anomalies and hemorrhages. Since the obesity is general, the disease should not be confused with painful lipoma. Very often a diagnosis of rheumatism or hysteria is made, as the patients may look well, yet constantly complain of pain. The treatment calls for rest in bed, followed by baths, massage, exercise and antifat diet. The only lesions which the author could find in excised portions of the skin were an abnormal increase of fatty tissue in the cutis. Probably this infiltration, together with the stasis of blood and lymph, is responsible for the pain. In some cases lesions of the thyroid, hypophysis and of Goll's tract were found, but it is doubtful if they bear any etiological relations to the disease.

Trypanosoma Disease in Man.—The organism known as *Trypanosoma* has for some time played an important role in animal pathology, and isolated cases of this infection in man have been observed for two years. It is now generally conceded that there are two distinct forms of the disease, depending on the localization of the germ: trypanosomasis proper and the sleeping sickness of negroes. In a case of the former, observed by A. GUNTHER and C. WEBER (*Münch. med. Woch.*, June 14, 1904), the chief symptoms were: A chronic course extending over years, recurrent periods of irregular fever, gradual loss of strength and anemia, local transient edema, a peculiar affection of the skin, swelling of the liver and spleen, increased pulse, occasional dyspnea and an irritability of the vascular system. The skin manifestations were irregular, red spots on various parts of the body, which disappeared on pressure. An absolute diagnosis can always be made by finding the worm-like parasite in the blood during the febrile period. In addition, the blood may be injected into rats and apes, which are very susceptible. The leucocytes are generally diminished with a relative increase of the mononuclear elements.

Diagnosis of Typhoid Fever.—Statistics have been collected on all typhoid cases during the last eleven years by F. WESENER (*Münch. med. Woch.*, June 7, 1904), who gives the frequency of the ordinary symptoms as follows: Palpable spleen 60.4 per cent., roseola 78.5 per cent., diazo reaction 85.2 per cent., Widal reaction 75.1 per cent. It seems that the most constant symptom of typhoid is the diazo reaction and its absence during repeated examinations argues for some other disease. Its chief disadvantage is its occasional presence in non-typhoid conditions, and this also applies to the Widal, for the author obtained distinct agglutination also in some cases of malignant endocarditis, influenza, miliary tuberculosis and sepsis. Even improved bacteriological technic and special culture-media do not render the diagnosis always easy, especially since such closely allied diseases as paratyphoid have been recognized. The diagnosis of typhoid is also discussed by D. ROLLY (*Münch. med. Woch.*, June 14, 1904), who lays great stress upon the bacteriological examination of the blood. The technic is very simple: Twenty c.cm. of blood are removed from a vein at the elbow, mixed with liquefied agar and poured into Petri dishes. The colonies will develop in one or two days and can be identified with agglutinating animal serum. A positive result was obtained in 88 per cent., including a large number of early cases, where the Widal was still negative. The great drawback of the method lies in the fact that it is hardly applicable for the ordinary practitioner, since it necessitates a bacteriological laboratory. The blood may, however, be diluted with a suitable fluid which does not kill off the germs, and then be sent to a bacteriological laboratory. For this purpose the author recommends a solution of five grams of peptone and fifty of glucose in 100 c.cm. of water. Twenty c.cm. of blood mixed with twenty c.cm. of this sterilized solution will not coagulate and the germs will keep until the following day. In order to obtain a permanent typhoid culture for the Widal, toluol or formuol is added to a five-day-old culture. The agglutination occurs in the same dilution as with live germs, but somewhat later; it may be observed both micro- and macroscopically.

Tuberculous Pericarditis.—The rarity of this condition is illustrated by the fact that among 1,077 autopsies, performed at the University of Palermo, SCAGLIOSI (*Deut. med. Woch.*, June 9, 1904), found it present in only one instance. The patient, a woman of sixty years, had died as the result of a pyelonephritis. After death a moderate amount of fluid was found in the pericardial cavity and the lining membrane was irregularly studded with small nodules, which were proved to be tuberculous. No other tuberculous lesions were found and the writer thinks that the patient's age was the predisposing factor in determining this localization, for, as is well known, the cardiac vessels in the aged are more or less diseased and thus offer a point of lessened resistance to the invasion of the tuberculous process. That primary tuberculous pericarditis may exist as a disease entity is therefore claimed by the author to be a rational assumption.

Tuberculosis in the South of Ireland.—This portion of the British Isles has as yet been sadly neglected in the application of sanitary and hygienic methods. J. DARLEY WYNNE (*Brit. Med. Jour.*, May 28, 1904), states that unfortunately, according to the reports of the Registrar-General for 1902, it is shown that while in England and Scotland the death rate from all forms of tuberculous disease has fallen to a remarkable degree in the last thirty-nine years, in Ireland it has actually increased. In 1864, it was throughout the island 2.4 per thousand, whereas in 1900 it reached a maximum of 2.9 per thousand. In the urban districts, having a population of 10,000 and upward, the rate was 4.29 per thousand in 1901 and 4.1 in 1902. The highest death rate from tuberculosis was in Clonmel, where it reached a maximum of 6.5 per thousand in 1901. In 1903 it was somewhat lower, but still the rates were extremely high. If other diseases were proportionately high in this particular township the population would soon become extinct, but as a matter of fact, death from other causes is not in proportion to the tuberculosis death rate. The cause for this condition of affairs is to be found in the type of Irish cabin. One enters a yard outside of the house and is obliged to go to the front door through a pond of filthy wet manure. The interior of the cottage is lighted by a dim light in which one can, after becoming accustomed to the gloom, see from six to a dozen half-naked children huddling over the embers of a peat fire. The floor is of mud and damp. There is but one window; this serves to keep out the air, for it is always shut. Contrivances which look like sailors' bunks are fixed against the wall in an inner room. They are carefully curtained to keep out light and air and are smothered in dirty bedclothes. A single window lights this room. This is where the unfortunate consumptive spends his last hours of life and where he breeds millions of germs for the remainder of the family to die from later on. In towns of the type of Clonmel there is no overcrowding. The backyards are about 20 feet long by 15 feet wide. In one corner, there is usually a faucet through which the town water supply can be obtained. Beneath it the trap is almost always defective and the yard is ill and irregularly paved. Of drainage systems, both for human and animal excrement, there is usually not the slightest trace. The receptacles in which this material is contained, are emptied at irregular and inadequate intervals, since the authorities do not oblige land owners to attend to this important factor. By a most pernicious arrangement, the filthy material, when these pits are cleaned, has to be removed directly through the house. It is probable that the horse and cattle fair, which takes place every month in Clonmel, is a very important factor in making the mortality from tuberculosis so high. Vast numbers of cattle are herded together for hours all over the principal streets and up against the shop fronts, and when the day is wet, the filthy condition of the roads makes them impassable. The milk supply of these towns is probably a further factor in spreading the disease, unless the views of Koch be correct, for vast numbers of the herd are infected with tuberculosis, no effort being made to regulate this part of the food supply of the commonwealth.

Atypical Lymphatic Leucemia.—A most peculiar case of lymphatic leucemia has been observed by A. WOLFF (*Wien. klin.-therap. Woch.*, June 26, 1904). The blood examination at first suggested pernicious anemia, since the red cells were below one million and the leucocytes not numerically increased. The absence of deformed and nucleated cells and the preponderance of large mononuclears made a leucemia of lymphatic type more probable. The clinical symptoms were only those of anemia and at autopsy the lymph nodes were atrophic rather than swollen. The diagnosis was, however, settled beyond doubt by the presence of lymphatic changes in bone-marrow and liver. In a second similar case there were two million cells, a normal number of leucocytes, of which 50 to 75 per cent. were mononuclear, a large spleen and a very chronic course with remissions.

Herpes Zoster in Pneumonia.—In 30 to 40 per cent. of all cases of croupous pneumonia, B. RIEHL (*Münch. med. Woch.*, June 21, 1904) found a well-marked herpetic eruption. The male sex seems to be affected more often than the female. Usually one and

the same individual is affected only once and the eruption generally makes its appearance on the third or fourth day of the disease, in the area of the second and third branch of the fifth nerve, preferably the infraorbital. Quite exceptional locations are about the eyes, the forehead, neck, anal and coccygeal regions and the extremities. During infancy and old age herpes is hardly ever seen. It is a noteworthy fact that mild cases show the most abundant vesicles, while severe and fatal cases are almost free from skin lesions, so that they possess prognostic importance.

Metabolism in Chlorosis.—The metabolic changes which occur in chlorotic patients, as manifest by the examination of urine and feces, may be summed up as follows, according to G. VANNINI (Virchow's Archiv, Vol. 176, No. 3): The urine is generally normal as far as amount, specific gravity, molecular concentration and acidity are concerned, but abnormal in that a retention of nitrogenous principles seems to occur and that these different principles bear an abnormal relation toward each other. The amount of ether sulph. acid is not increased, while an excess of neutral sulphur is common; the earthy phosphates are diminished and the amount of chlorides varies. Subnormal amounts of chloride are found in the fecus, but the amount of ash and its contents of lime, magnesia, soda and potash, does not suffer any change.

Pseudoleucemia Lymphatica.—(*Gazz. degli ospedali*, June 19, 1904.) A male patient, aged fifty-seven years, with negative family history, denying syphilis and alcohol developed painless swellings of the lymphatic glands of the neck, with some constitutional symptoms, both of which disappeared completely in a week. The glandular enlargement returned, and the neck became much enlarged. Occasional chills and increase of temperature were noted. Emaciation and anemia developed. Physical examination was negative, except the presence of a hemic murmur. The white corpuscles were 10,000; the red, 3,200,000. Glandular swelling increased; there was a higher temperature, physical weakness, a trace of albumin in the urine. The spleen gradually increased in size. Death occurred three months after patient entered the hospital. Autopsy revealed the following facts: Marked anemia of all organs. Fatty degeneration of heart and liver, spleen much increased in size, pulp soft, red, with four or five areas of infarcts. Kidney enlarged, pale somewhat sclerotic; medulla of long bones, lymphoid, pale red, not fatty. The lymphatic glands are enlarged, the peribronchial and peritracheal form a hard mass. Other enlarged glands show increase of fibrous tissue, or parenchymatous enlargement. Under the microscope marked change of structure was seen, notably endothelial cells, large and small lymphocytes and eosinophiles. Some areas closely resembled lymphosarcoma.

THERAPEUTICS.

The Crisis and Treatment of Pneumonia.—A new method for treating this disease is advocated by W. J. GAILBRAITH (*Jour. Am. Med. Ass'n.*, July 9, 1904), which is not offered as a specific, but is claimed by the author to have greatly reduced his former mortality. His experience leads him to believe that the so-called pneumococcus may be associated with the etiologic factors of pneumonia, but is not its specific cause. The first attention rendered the ordinary cases admitted to his hospital (in Sonora, Mexico), is a warm bath and a saline cathartic. Quinine and iron are given under the following indications: When the temperature has reached 105° or over, 60 grains of quinine sulphate are administered, followed in one-half hour by half this amount, 30 grains, and in another half hour, by 15 grains. At this time the administration of tincture of iron chloride is begun in doses ranging from 7 to 15 minims, depending on the date of the disease and the condition of the heart. On the first or second day of the attack, 10 minims are given, and this is increased one or two drops each day up to the sixth or seventh, unless the pulse remains full and strong. When the temperature is 104°, the author gives 50 grains, and follows the same course. When it is 103°, 30 to 40 grains are given. During convalescence combinations of the following were found to be of value, elixir of iron, quinine, and strychnine, guaiacol and cod liver oil. But best of all at this time is thorough ventilation and sunlight, with plenty of milk, eggs and beefsteak. The term crisis he considers a misnomer, and presents pneumonic cardiectasis as a more descriptive term, which attracts attention specifically to the overdistended and disabled heart. Stimulants are contraindicated during this time, as they increase the mechanical conditions that are distressing the patient.

A Case of Tuberculous Leprosy.—There are said to be over one thousand lepers in Russia, although the exact number is not known, and they are mostly to be met with in the villages. G. LELEWSKY (*Prakt. Vrach*, Nos. 9 and 10, 1904) considers leprosy as a malignant constitutional disease, almost always of a chronic nature. The case reported by him was that of a man of twenty-seven years, who became ill five years before at sea during a storm, when he caught a severe cold. The advance was gradual though well marked. The skin presents at places thickened spots of a dark bronze color, especially noticeable at the tip of the nose. There is an almost complete absence of hair over the eyebrows and lashes. The ears and lips are considerably thickened; the face presents the typical leonine appearance. There is a beginning keratitis in both eyes, the commencing pannus leprosus. The skin of the arms is covered here and there with spots of a dark bronze color, same to be seen on the feet. There was a large grayish-white spot over the palate extending to the uvula. The epiglottis is thickened, and of the same color. Patient complains of dryness in the mouth and throat. As regards treatment, patient was given ol. chaulmoogra in doses of 5 to 20 drops three times a day, but as he was later lost sight of the effect of the medication could not be watched. It might add to the interest of the case if the author had attempted to prove the existence in this case of the lepra bacillus, so that the diagnosis might have been established beyond any peradventure.

Value of Water in Disease.—Attention is called to the importance of a plentiful administration of water, especially in those diseases accompanied by a rise in temperature, by E. HOMBERGER (*Berl. klin. Woch.*, June 20, 1904). For by this method the most distant cells may be reached and affected. Water is the great natural curative measure and the easy method of application should not cause it to be neglected. As cellular pathology demands a cellular therapy, this agent seems to be the most rational means to attain that end. In the presence of fever especially, the administration of water should be made a particular effort, as there is an insufficient quantity present in the system, and as the body is slow to give this up, a diminution in the quantity of sweat and urine results. The author claims that perspiration is only restored when the temperature begins to drop and the superfluous water is no longer needed. Where toxins have circulated in the blood for a considerable period, the giving of water is of great value, but where these products leave the system rapidly and unite with the cells, it can be of little avail.

Treatment of Snake Bites.—Since 1869, permanganate of potash has been used as a chemical antidote in cases of snake-bite. An experimental investigation of the value of this substance has been made by SIR L.

BRUNTON, SIR J. FAYRER, and L. ROGERS (*Proc. Royal Soc.*, May 28, 1904). Brunton devised an instrument that might be used in cases of snake-bite. It consists of a lancet-shaped blade about half an inch long, long enough to reach the deepest point of a bite by the largest snake. It is set in a wooden handle about an inch and a half long, which is hollowed at the other end so as to form a receptacle for the permanganate. Two wooden cups are fitted over the ends of the instrument, one to keep in the permanganate, and the other to protect the lancet. Such an instrument might be carried in the pocket and used by even the ignorant natives of the snake-infested locality. The plan proposed is to make a free opening at the site of the bite and to rub in crystals of permanganate. The limb is first surrounded with a tight bandage above the bite. The puncture of the teeth should be freely cut into and the crystals of permanganate introduced and rubbed about, a few drops of saliva being added. The value of the above method of treatment was experimentally tested on animals. The venoms of nine varieties of snakes were employed. In the cases of each ten or more lethal doses, and in the most of them twenty lethal doses were neutralized by very small quantities of permanganate in solution, and thus rendered harmless. These experiments prove that this agent acts on every class of snake venom and renders them inert. The experiments were performed on rabbits, pigeons and cats.

PHYSIOLOGY.

Secretion of Acid by the Kidney.—A study of the mechanism by virtue of which the kidney excretes an acid urine from the alkaline blood, was made by A. R. CUSHNY (*Jour. of Physiol.*, June 30, 1904). The latter found that the reaction of the urine varies within strict limits in diuresis; it is never alkaline to phenolphthalein nor acid to methyl-orange, and thus corresponds approximately to the interval in reaction between mono- and di- sodium phosphate. The intravenous injection of most saline diuretics is followed by a marked fall in the percentage acidity, partly because the phosphates are present in only small amount, and partly because the absorption in the tubules is deficient. Phosphates injected intravenously give an acid reaction to the urine which is especially marked when the diuresis is partially prevented by increasing the absorption of the tubules. This is explained by the hydrolytic dissociation of the phosphates of the glomerular fluid, which permits of the absorption of the cation along with hydroxyl or carbonate anions; these are capable of permeating the epithelium, while the phosphate anion fails to penetrate it so freely and remains in the tubules along with the hydrogen cations replacing the original ones. The essential factors in the secretion of acid urine are (1) the presence of salts in the glomerular fluid which are capable of extensive hydrolysis and of which the cations can permeate the epithelium, while the anion fails to do so in equal measure, and (2) insufficient absorption in the renal tubules. The phosphates alone of the salts examined fulfil these conditions completely. The carbonates fail to do so because the anion is absorbed, and the borates satisfy the condition only in relation to phenolphthalein, since the anion is too weak to compete with the stronger anions of litmus.

The Coagulation of Milk.—The chemistry of the phenomena that underlie and influence the coagulation of milk has been carefully worked out by A. S. LOEVENHART (*Hoppe-Seyler's Zeitsch.*, March 5, 1904). Milk is curdled by the following causes: (1) Turning sour upon standing; (2) the latter together with heating; (3) the addition of acids to fresh milk; (4) fresh milk heated to 110° to 130° C. in a closed tube; (5) fresh milk heated with $CaCl_2$; the addition of rennet to fresh milk; (7) the heating milk to which too small a quantity of rennet has been added to effect coagulation; (8) milk coagulates during a storm (the cause of this is not yet understood); (9) electrolysis. In 1, 3, 4, 8 and 9, the coagulation is to be attributed to an acid which liberates casein from its union with calcium. According to Hammarsten, the effect of rennet is to cause a splitting of casein into lactalbumin and paracasein. This is very similar to casein and differs from it in being coagulated by calcium salts at ordinary temperature, while casein requires higher temperatures. The metals may be divided into three groups with respect to the action of this salt upon casein and paracasein. The first group which contains the strongest metals, as sodium, precipitate neither casein nor paracasein. The second group, which contain lithium, etc., precipitate paracasein rapidly from its solutions at room temperature, but casein only after standing a long time at 40° C. or higher. The third group coagulate both bodies promptly at room temperature, and include all the other heavy metals, as iron. The precipitating power increases progressively with the transition from the strongest to the weakest metals. The precipitation of paracasein by colloidal solutions as acids, salts and alcohol is brought about more easily than that of casein. There is no evidence that casein and paracasein are distinct substances, for all their differences are of a physical nature and indicate that these two substances are modifications of one and the same thing. Decalcified milk is coagulated by salts of the following metals; calcium, strontium, barium, etc., which fact indicates that probably the coagulation if mild is largely dependent upon a change in the arrangement of its mineral constituents. Acids are only the indirect cause of coagulation; the direct cause is calcium. The addition of ammonium oxalate to acid milk inhibits coagulation.

The Production of Hemolysins and Agglutinins by the Stromata and Liquid of Laked Corpuscles.—A series of experiments were performed by G. N. STEWART (*Am. Jour. Physiol.*, June, 1904), with the view of determining the effect of the injection of the stromata and of the substances which escape from the corpuscles respectively, in hemolysins, caused by various laking agents as regards the production of specific agglutinins and lysins. He found that the stromata and hemoglobin, containing liquid of colored corpuscles, laked by various agents (water, freezing and thawing, heat, saponins, foreign serum), cause, when injected into animals of a different species, the production of specific agglutinating and hemolytic substances. In general, the agglutinating effect is most marked after the injection of liquid. But the results do not warrant the conclusion that in the intact corpuscle the agglutinogen (the substance which causes the production of agglutinin) is all in the stroma, and the hemolysinogen (the substance which causes the production of hemolysin), all in the cellular contents (in Nolf's Sense). Corpuscles fully fixed by formaldehyde cause, on injection, the production of specific agglutinins, and to a smaller extent of specific hemolysins. Such corpuscles are capable of being agglutinated by specific sera.

The Comparative Physiology of Peristalsis.—A study of the peristaltic movements in the lower organisms (worms, etc.), leads W. BIEDERMANN (*Pflüger's Archiv.*, May 21, 1904), to conclude that direct muscular conduction plays no rôle in these phenomena. They are rather bound up with the integrity of the central nervous system and are the result of progressive segmental reflexes, in which any passive stretching of the muscle of any segment produces reflexly a contraction of the circular muscle, and probably a synchronous relaxation of the longitudinal muscle.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the MEDICAL NEWS will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

SATURDAY, JULY 30, 1904.

CANCER ETIOLOGY AGAIN.

SCARCELY has one apparently important contribution to the question of the etiology of cancer been made before another is announced that undoes something at least of the supposed significance of the previous work. At the beginning of the present year, as the result of an investigation conducted by a special commissioner Doctors Farmer, Moore and Walker in London announced that the real factor of cancer consisted in a transformation of the cells of normal adult tissues into modified reproductive tissues. Since reproductive cells are selected very early in embryonal life for the special purpose of carrying on the race, a reversion of other cells to this type later on in life might seem impossible, but the observations of these investigators apparently demonstrated that such a transformation actually took place. There is a diminution of the chromosomes in the cells of malignant tissue, just exactly the same as is noted in reproductive cells.

The mitotic changes in the cells of cancer have occupied attention for a considerable period. It has been recognized that the appearance of these cell changes had a special significance. Mitosis occurs much more frequently than in normal tissue, even when it is undergoing regeneration and certain anomalies in the mitotic figures are characteristically present. For a while it was thought that this heterotype mitosis, might be of a diagnostic value, but this idea is no longer accepted. The declarations of Farmer, Moore and Walker recalled attention to them and seemed to find the explanation of the whole process of malignancy in the anomalies observed in them.

The report of the cancer research fund of the Royal College of Physicians and Surgeons of London, which has been recently issued, does not accept the conclusion with regard to the explanation of cancer as a reversion of cells to the reproductive type. In the section on the cytology of cancer it is said that after careful observation the number of cells exhibiting mitotic changes varies very considerably in different tumors. The number of cells observed in mitosis bears no relation to either the rapidity of growth of the tumor or to the tendency for it to produce metastasis. In a word, although the observations with regard to the occurrence of anomalous mitoses are confirmed, there is no distinct relation between this cellular reproductive process and the malignancy of the tumor in which it occurs. In rapidly growing tumors with tendencies to degeneration it may be hard to recognize the presence of mitotic cells in any number.

In another way the question of the possibility of reversion to reproductive type causing malignancy has been carefully studied. Portions of tissues removed from the testes and ovaries of living animals that are known to be liable to cancer have been transplanted to other tissues without any serious result and absolutely without any sign of invasion of the surrounding parts by this foreign type of tissue. These observations, of course, only confirm what is known with regard to the transplantation of ovarian tissue, for in a large number of instances gynecologists have deliberately transplanted portions of the ovaries without producing any serious results.

This is the negative side of the report. The positive side is of distinctly as much interest. The zoological distribution of cancer is now being studied to good effect. Specimens obtained from nearly all the various forms of domestic animals are described in detail in the report. While, of course, it has been known that the cow, the dog, the horse, the sheep, the cat and the mouse are especially liable to suffer from cancer, it is now definitely ascertained also that the warmer blooded birds and the cold blooded fishes

are no exceptions to this rule. Specimens of cancer from the hen are shown, as also some from the trout. Wild and domestic animals seem to suffer equally from the disease, though, of course, there are more opportunities for its observation among the domesticated. An explanation for the occasional transmission of cancer, such as occurs from one lip to the other in epitheliomatous cases is to be found in certain experiments upon mice. Borrel's success in transplanting true cancer from mouse to mouse gave great hopes of an explanation of cancer etiology being reached in this way. The cancer research commission repeated these experiments in some 250 cases with a successful result in over 25 per cent. of the cases. If the tumor tissues were exposed to a temperature equal to that of the human body for twenty-four hours between the time of its removal from one animal to implantation in another, no successful results were obtained. Mechanical disintegration of the tissue by crushing in a mortar also prevented successful transplantation.

The nucleus of the cancer cells still continues to be a point of greatest interest. Some years ago von Hansemann, of Berlin, announced that the nucleus of cancer cells was characterized by having less chromatin than normal. It was somewhat in line with this idea that Farmer, Moore and Walker's work suggested the reason for this in a diminution of the number of chromosomes, because of reversion to the reproductive type. The present report confirms these observations with regard to the hypochromatic nucleus, but suggests that certain appearances within the nucleus are also important. In many carcinomata nuclear figures exist, which would seem to suggest that a conjugation of cells had taken place. If this were the case it can readily be understood that a new cycle of life and development would be begun, and that luxuriant reproduction of such tissues might be expected. Such cells would be likely to grow independently of their environment in the tissues and take on the essential characters of malignancy. They would infiltrate and deprive other tissues of nutrition, and if carried to a distance in the fluids of the body continue their independent existence producing the typical metastases. Whether this is to prove a pregnant hint for the solution of the most important problem, the etiology of cancer, remains to be seen. Once more we depart from the nature of micro-organisms to suspect some essential change in the vitality of the cells.

FORMS OF ARTHRITIS.

There is no doubt that so-called rheumatism in many of its forms is a motley assortment of most intractable diseases. Recently the general public has been treated to a book on a rheumatic man's adventures, the title of which is "Being Done Good," with Comments on the Advance made by Medical Science during the past 5,500 years in the Treatment of Rheumatism. The author claims to have tried every thing under the sun that physicians have suggested to him, or that he has obtained from tradition, or found in books, yet without obtaining any relief.

There is little question that there are many others who could tell a somewhat similar story, and there is even less doubt that this state of affairs will continue until it is more generally recognized and thoroughly appreciated that "rheumatism" is a very general term that has been made to cover a multitude of affections, most of which bear no relation to true rheumatic arthritis.

At the present moment much attention is being devoted to uric acid as a causative factor in rheumatic manifestations. There is even a *Uric Acid Monthly* (save the mark!), a proprietary sheet devoted entirely to the rubbish written about the so-called uric acid diathesis as the groundwork of nearly all the ills to which flesh is heir and many others in addition.

If the advertisements for various proprietary preparations, of varying hues of ethical coloring, are to be trusted, uric acid is the most important pathological element in the human body. If Macaulay's traveler from New Zealand should sometime, while nosing around the foundations of the Brooklyn Bridge, and the cornerstones of churches that are being laid at the present time, find copies of our present-day newspapers, especially the advertising columns, he will be sure to think that uric acid was the special curse of our generation and that ours might very well have been termed the uric acid age in medicine.

At the last meeting of the American Medical Association, however, nearly every one who took part in the discussion of arthritis deformans disclaimed utterly any belief in the uric acid theory of the origin of rheumatic or arthritic manifestations, and there was no doubt at all that the audience was thoroughly in sympathy with these nihilistic opinions, now voiced for many years in the Medical News.

On the other hand, there was quite as general an expression of opinion that true rheumatic arthritis can be recognized by the fact that it

leaves no trace of its presence in the joints. If lasting joint changes have occurred it is a sign that some secondary infection has been at work. Rheumatic polyarthritis has as distinct a tendency to run a definite course and get entirely well as does pneumonia, which it resembles in many other respects.

With regard to arthritis deformans itself, there remains the question whether this name may not itself cover a group of diseases rather than a single pathological entity. While the disease has attracted attention only in comparatively recent years its history goes back to the very earliest times, signs of its occurrence having been found on the bones of mummies and other preserved bodies all down the centuries, exactly in the form in which it is now observed. The changes in the spine which are especially characteristic of one clinical form of arthritis deformans have been found and leave no possible room for doubt in this matter. As seen at the present time, arthritis deformans exists in an atrophic and hypertrophic form and the question is still in doubt whether these are the same or different pathological processes. Occasionally atrophic and hypertrophic lesions are found in the same subject. This is rather rare, however. Good authorities insist that they have never seen one form of the disease change into the other. Like the question of hypertrophic and atrophic cirrhosis of the liver, there would seem to be need of further careful clinical observations in order to decide the question.

That all the deforming changes in joints are not due to arthritis deformans has now come to be very generally recognized. In some of the cases, especially where only one or two joints are involved, other forms of infective arthritis are more than suspected. While a monarthritis of the hip or shoulder-joint is not uncommon in older people and is considered to be a manifestation of arthritis deformans, in younger persons the confinement of the disease to a single large joint must always give rise to a suspicion of infection by some micro-organism, very frequently the gonococcus. The typical signs of arthritis deformans are the involvement of the small joints of the fingers and toes and a tendency to invade the submaxillary joint and the joints of the cervical spine. There is a general tendency to believe that the disease is infectious in its nature and at least one micro-organism has been isolated, which on injection into animals has produced deformity of joints, but the results of experimentation are as yet very fragmentary and untrustworthy. This, like other questions connected with the disease, must still remain as a subject for further investigation.

Unfortunately the treatment does not prove very promising. The warning not to do harm is the most important element in present-day therapeutics. It has been too often the custom to limit the diet of patients suffering from arthritis deformans, and the consequence has been a lowering of the general condition, which has invariably done harm rather than good. The appetite is usually a safe guide, though digestive disturbances must be corrected, and this may require careful selection and limitation of some one of the three ingredients of a mixed dietary, fats, carbohydrates or proteids. On the other hand, it is very clear that the salicylates, if used for any considerable period, do not relieve pain, while they do produce a tendency to anemia likely to react upon the patient's general health. Of the modes of active treatment the most important procedures consist in hot applications of some variety. Hot air and hot baths are the most helpful, though these alone are palliative rather than curative. As soon as the acute stage of arthritis deformans has passed, passive movement and massage are of value. The index for their employment must be the amount of pain they cause. Where pain is severe they are contraindicated. The prognosis of the disease is not as hopeless as has been thought, although there is a distinct liability to the recurrence of acute exacerbations of the disease, each one of which leaves the patient somewhat more helpless than before. The employment of the word rheumatism with regard to these recurring attacks has given a very bad name to a benign affection and has utterly confused the true therapeutics of the group of joint diseases. It has also often blinded the eyes of the young clinician and prevented his seeking for differentia in diagnosis.

ECHOES AND NEWS.

NEW YORK.

Infant Mortality High.—The Board of Health is having about 100 persons, including the entire summer corps of doctors and nurses, investigate the high mortality now prevailing among infants. In the week ending last Saturday there were 279 more deaths from diarrheal diseases than in the corresponding week of 1903, and this increase of infant mortality advanced the death rate for the week to 23.46.

The Paterson Drainage Canal and New York Bay.—Under the caption, "The Proposal to Make Our Bay a Cesspool," the *Sun* writes: "There are many

thousands of New Jerseyites who transact business in this city. They sleep on the other side of the North River and vote there. But apart from their families their interests lie on this side. When they travel they put 'New York' after their names on hotel registers. For all practical purposes they are New Yorkers. But for the existence of an imaginary line separating the two States, the places where they live would be a part of the greater city. What do these people think of the fight which is being made to drain a number of cities in northern New Jersey into our harbor and place the metropolis in peril of disease? Dr. Lewis, the head of the New York State commission which investigated the subject recently, says: There is one thing on which the commission, I think, is already fully agreed: that the waters of the bay and the rivers are already carrying all the sewage they ought to carry; and I have no doubt that the report of the commission will urge that the existing conditions at least remain stationary. While the old sewers cannot well be fitted with apparatus for the sanitary treatment of sewage, no new sewers should be opened without such apparatus. He added that the New Jersey scheme would put an open cesspool under our very noses. Fortunately, the decision of the New Jersey Supreme Court in favor of the constitutionality of the plan does not settle anything. New York will carry the matter to the Court of Errors and Appeals. And if beaten there, the final engagement will take place in the United States Supreme Court. An individual has to respect the rights of his fellow man. It is quite absurd for a community to imagine that it has any more right than an individual to ignore the safety, the peace of mind, the comfort of the neighboring community.

PHILADELPHIA.

Polyclinic Hospital.—Dr. William Sweet has succeeded Dr. H. F. Hansell as professor of Diseases of the Eye. Dr. Hansell, who resigned, becomes professor emeritus.

Death of Superintendent Smith.—Robert M. Smith, superintendent of the Philadelphia hospital, died July 20 from gastritis. O. A. Bohler, house agent, is at present acting superintendent.

Hospital for the Treatment of Cancer.—A number of physicians of this city, aided by several public-spirited lay citizens, contemplate founding a hospital for the treatment of malignant disease. A preliminary meeting has been held to formulate plans for the undertaking. The hospital is to adhere to no one method of treatment but any and all means that promise results will be tried.

Report of Food Commissioner Warren.—The report of State Dairy Food Commissioner Warren for 1903 shows that 1800 prosecutions were ordered because of infringements of the Pure Food Laws. From these were collected as fines and costs the sum of $93,450. The Pennsylvania Pure Food law of 1895 is said to be the most effective in the United States, but suggestions are made for its improvement so that prosecutions can be more readily brought to termination.

University of Pennsylvania.—The present medical hall of the University is to be renamed Logan Hall, in honor of a former trustee, and largely given over to other work. Most of the medical teaching will be given in the new medical laboratories; the old building will be used for anatomy, didactic lectures in surgery, and chemistry. The remainder of the building will be occupied by the school of finance.

CHICAGO.

Taking Care of the Children.—In 1870 the population of Chicago, by the United States census, was 306,605, and there were 4,600 deaths of children under five years of age reported. These figures show a proportion of something over 150 children's deaths in every ten thousand of the population. Thirty years later, that is, 1900, the same authority fixed Chicago's population at 1,698,575, and there were 8,285 under five years of age deaths reported. These figures show a proportion of less than 49 children's deaths in every ten thousand of the population, a decrease of more than two-thirds. A further analysis of the statistics shows better results for later periods. During the ten years 1884-1893 there were 89,633 deaths under five years of age in the City of Chicago. The average yearly population of this period was 954,676; therefore, the deaths under five years were 93.9 in every ten thousand of the population. During the ten years 1894-1903 there were 88,816 such deaths—or 817 fewer than in the first period The average yearly population of this latter period was 1,609,110 and the deaths under five years were, therefore, 55.2 per 10,000. These two sets of figures show a decrease of child mortality of much more than one-third (41.2 per cent.) in a single decade. While the average population increased 654,434, or 68.5 per cent., the under-five-years deaths were actually fewer.

Dinner to Dr. Earles.—A dinner was given to Dr. W. H. Earles, Milwaukee, Wis., July 16, at 8 P.M., at the Republican House. Dr. Wm. A. Evans, of Chicago, acted as Toastmaster. Toasts were responded to as follows: "Within Mailing Distance," by Rev. P. Fitzgerald; "Our Boyhood Days," by Mr. J. Emil Bench; "On the Campus," by Mr. John L. O'Connor; "Corduroy Roads," by Dr. M. H. Fisk; "Burning the Candle," by Dr. Truman W. Brophy; "Helpmates," by Prof. R. W. Sommer; "Colleagues," by Dr. G. A. Kletsch; "The Citizen," by Hon. David S. Rose, Mayor of Milwaukee; "The Surgeon," by Dr. John B. Murphy.

Suits Against Delinquent Milk Dealers.—Suits against 314 delinquent milk-dealers were successfully prosecuted during the week. The highest penalties, $50.00 and costs, were inflicted on two classes of offenders—those selling the low grade milk after warning, and those found guilty of using preservatives, chiefly formalin.

Dairy Inspection.—Dairy inspection improves in its results each week. Farmers offer to make affidavits that they will abandon the feeding of "wet malt," if allowed to ship their milk into the city, and in other ways show the good effect of the inspections. Of 146 dairies inspected during the week, 20 were found feeding the objectionable material, but promised to quit when the matter was fully explained to them. Sanitary instruction is even more important than sanitary legislation.

GENERAL.

New Sewage System for Paterson.—An opinion filed in the New Jersey Supreme Court, July 23, sustains the constitutionality of the law commonly known as the Passaic Pollution act. This law establishes a sewage system along the Passaic Valley, and provides for the construction of a trunk sewer from Paterson to the New York Bay at an estimated cost of $9,000,000.

Dispensary for Tuberculosis in Ohio.—Trustees of Western Reserve University have voted to establish an anti-tuberculous dispensary in connection with the medical school. The dispensary will register those who are infected with the disease, locate houses in which tuberculous people live, educate the people along fundamental hygienic lines, and its agents will visit the homes of the sick, giving instruction in the care of those afflicted with the disease.

Typhoid in the Navy.—The Navy Department received a despatch on July 23, from Rear-Admiral Barker

at Trieste, giving the first official information which has been received in regard to the typhoid fever epidemic among the officers and men of the American fleet. The despatch is as follows: "Battleships and Mayflower leave for Fiume to-morrow. European squadron separate. Mayflower will return to look after typhoid cases in hospital. Chaplain Isaacs, Capt. Dion Williams, Lieutenant Hudgins, Lieutenant Clement, Ensign Timmons and two sailors doing well."

University of Vermont.—The corner stone for the new medical building for the University of Vermont, was laid July 5, by Hon. John G. McCullough, Governor of Vermont. Short speeches were made by President Mathew Henry Buckham of the University; Dr. Henry C. Tinkham, Dean of the Faculty of Medicine; Dr. A. F. A. King, Professor of Obstetrics, and Ex-Governor U. A. Woodbury, who is one of the Alumni of the Medical Department. The graduating exercises occurred July 6, when fifty-five candidates received the degree of Doctor of Medicine. Those receiving honorable mention were Dean S. Drake and Thomas S. Brown of New Hampshire; Henry Raymond Biggar of New York; G. L. Closson of Vermont, and George B. O'Connell of Maine. Dr. O'Connell was president of his class and Dr. Biggar was elected valedictorian. The commencement being the one hundreth anniversary of the first in the University was a grand affair. Many alumni and former students were present.

Russian Hospital Trains.—The whole of the Manchurian and Siberian railway lines are systematically divided into sections and numbered. Hospital trains replete with the best surgical and other appliances obtainable are apportioned to these sections. The staff of each train includes three or four doctors, from six to ten nursing sisters of the Red Cross Society, and from thirty to forty hospital assistants. Each train has accommodation for two to three hundred wounded and sick.

Medical Society of the Missouri Valley.—The seventeenth annual meeting of this association will be held Thursday and Friday, August 25 and 26, at Council Bluffs, Ia. An entertaining programme is being prepared, and the adoption of a new constitution and by-laws, placing this society in line with the American Medical Association will make this one of the most important meetings in its history. The Committee on Arrangements extends a cordial invitation to the profession, and announces an excursion to Manawa Park on Thursday evening, where a smoker will be given for the entertainment of the visitors. Headquarters and meeting-place will be at Grand Hotel. Following is the preliminary programme: The Clinical Importance of the Reflexes, by H. Douglas Singer, Omaha; Congenital Dislocation of the Hip, by J. W. Cokenower, Des Moines; Recurrent Dislocation of Shoulder Joint and Its Treatment, by A. D. McKinnon, Lincoln; High Forceps Operations, by Mary Strong, Omaha; Temperature, Its Significance and Treatment, by A. E. King, Blockton; Treatment of Prolapse of Rectum, by A. C. Stokes, Omaha; Two Gall-Bladder Cases Presenting Some Unusual Conditions, by Harry Everett, Lincoln; Some Recent Progress in the Surgery of the Large Intestine, by J. E. Summers, Jr., Omaha; The Ocular Manifestation of Syphilis, by W. L. Kenney, St. Joseph; Affections of the Lacrimal Apparatus with Deformities Repaired by Parafin Injections, by Flavell B. Tiffany, Kansas City; Is It Mental Trauma? by S. Grover Burnett, Kansas City; Tinea Trichophytina, by R. C. Moore, Omaha; Treatment of Diabetes, by Le Roy Crummer, Omaha.

The American Association of Obstetricians and Gynecologists.—This Association will hold its seventeenth annual meeting at the Hotel Monticello, St. Louis, Tuesday, Wednesday, Thursday and Friday, September 13, 14, 15 and 16, 1904, under the following administration: President, Walter Blackburn Dorsett, St. Louis; vice-presidents, Aaron B. Miller, Syracuse, and William D. Haggard, Nashville; secretary, William Warren Potter, Buffalo; treasurer, Xavier O. Werder, Pittsburg; executive council, Edwin Ricketts, Walter B. Chase, A. Vander Veer, Lewis S. McMurtry, L. H. Dunning and Rufus B. Hall. The Hotel Monticello has been selected for the headquarters of the association, the management of which should be addressed concerning rooms and rates. The following list of papers has been offered: President's Address, by Walter B. Dorsett, St. Louis; Retrodisplacements as a Cause of Sterility; report of pregnancies following the Alexander operation, by Herman E. Hayd, Buffalo; Cyst Adenoma of the Pancreas, by L. H. Dunning, Indianapolis; Some Clinical Reasons for Advising Early Operations for Fibroid Tumors of the Uterus, by Rufus B. Hall, Cincinnati; Operative Treatment for Relief of Painful Menstruation in Virgins, by W. A. B. Sellman, Baltimore; The Relative Merits of Bag and Metal Dilatation, of Cervical Incisions, and of Cesarean Section in Cases of Accouchement Forcé, by E. Gustav Zinke, Cincinnati; Pseudomembranous Tubercular Peritonitis, by H. W. Longyear, Detroit; The Treatment of Acute Perforated Gastric Ulcer, by Henry Howitt, Guelph; Shall We Remove all Fibroid Tumors of the Uterus Upon Diagnosis? by Thomas B. Eastman, Indianapolis; Scar of Sigmoid Mesentery the Cause of Spastic Obstruction of the Bowels; with Report of Three Cases, by Hugo O. Pantzer, Indianapolis; Surgical Treatment of Cicatricial Atresia of the Vagina, by Charles G. Cumston, Boston; The Advantage of Limiting Artificial Interference in Obstetric Practice, by A. P. Clarke, Cambridge; Uterine Myomas, with Specimens, by Joseph H. Branham, Baltimore; Use of Antistreptococcic Serum in Septicemia and Scarlatina, with Case Histories, by A. G. Hamilton, Springfield, Neb.; An Unusual Case with Many of the Symptoms of Appendicitis, by Magnus A. Tate, Cincinnati; Conservation of the Natural Resistance of the Patient in Surgical Work, by Robert T. Morris, New York; Skeleton of an Ectopic Fetus Removed by Vaginal Cystotomy, by William D. Haggard, Nashville; Infantile Intestinal Diverticula, by J. W. Hyde, Brooklyn; Emergency Operations in Abdominal Surgery, with Cases, by A. Edwin Ricketts, Cincinnati.

Cancer Research.—The paper which the superintendent, Dr. E. F. Bashford, read before the general committee of the Cancer Research Fund in London, writes the *Post*, shows the wide and systematic process of the investigation by which it is hoped to discover the secret, and the cure, of this terrible affliction. Some important facts have been brought to light by the examination of tumors taken from various animals. Through the collaboration of private persons at home and abroad specimens of malignant new growths have been obtained from many lower vertebrates, including fourteen cases of carcinoma in fish. Two cases of malignant new growths in fish possess a special value, because derived from marine fish living in a state of nature, and similar interest attaches to a spheroidal-celled carcinoma discovered in a wild mouse. These are the first authenticated cases of cancer in wild animals. More than 2,000 specimens have been examined, secured from various subjects: Human, 266; horse, 116; cow, 99; dog, 247; cat, 43; pig, 8; frog, 6; bird, 13; mouse, 850; fish, 80; rat, 28; rabbit, 32; sheep, 8; goat, 7; bull, 1; miscellaneous, 329. In this way it has been proved that cancer pervades the whole vertebrate kingdom and presents constant fundamental characters. The

great diversity of the food, habitat, and conditions of life generally of the animals in which cancer occurs indicates that such external agencies have no causative influence. The origin of cancer has to be sought in the life-processes of the cells, and it has been demonstrated that a transplanted tumor will grow only on an animal of the species from which it was taken. There is much significance, too, in the discovery of the conjugation that occurs between the nuclei of cancer cells, as it points to the nature of the problem which has to be solved before growth can be prevented. Dr. Bashford's report goes on to say that there is no evidence to support the theory that certain countries or races of men are immune from cancer. This notion is ascribed to insufficient investigation. Thus the fact that there are more cancer cases in English than in Irish hospitals is due to the lack of competent medical supervision in the latter country. By the aid of the British Colonial Office, specimens of malignant new growths have been obtained from the natives of regions of Africa in which cancer was not known to exist, while through the Foreign Office, the Colonial Office, the India Office, the Egyptian Government, and private observers cancer has been found to be much more frequent in many tribes than it was suspected to be. Fortunately, there are no facts to support the widely spread belief that there has been an actual increase in cancer mortality. Dr. Bashford points out that among 1,786 new growths removed from the human subject in 1904, and supposed to be malignant, there were 127 in which the diagnosis was not confirmed by microscopical examination. In these the characters of malignancy were only simulated, and this, says the doctor, explains many reputed cures of cancer. Inasmuch as many malignant growths present no specific symptoms by which their nature can be placed beyond doubt, the report strongly advises the earliest possible operative interference, even in the case of new growths which may not appear to be malignant. There is no way, it appears, of positively proving them to be beneficient, a dictum which is likely to revive some almost forgotten apprehensions.

OBITUARY.

SIR JOHN SIMON, K.C.B., former president of the Royal College of Surgeons and of the Royal Society, is dead. He was born in London in 1816 and became senior assistant surgeon in the King's College Hospital, in 1840, when only twenty-four years old. Seven years later he was appointed lecturer in pathology at St. Thomas's. He soon established a great reputation by his writings on pathology and therapeutics, and began to devote his best energies to the work of sanitary reform. Being appointed Health Officer of the city of London, he was practically the father of most of the important sanitary legislation of that period. He pointed out the true moral of the several visitations of cholera, with which London was afflicted between 1845 and 1855 and so created a public sentiment which compelled the Government to take necessary precautions. For twenty-one years he held the post of central medical officer, and during that time presented a series of reports to the Privy Council, which may properly be described as invaluable. One of the most important of them was in defence of vaccination. British and European universities honored him with degress, and he was a member of innumerable medical and scientific associations. In spite of his activities in behalf of sanitation, his multifarious reports, and his professional occupations, he published many volumes on miscellaneous subjects, remarkable for their varied erudition and their admirable style. He devoted such leisure time as he could secure to the study of art, metaphysical literature and Oriental languages. Queen Victoria made him a K.C.B. on the occasion of her first jubilee in 1887.

CORRESPONDENCE.

OUR LONDON LETTER.

(From Our Special Correspondent.)

LONDON, June 25.

KING'S BIRTHDAY HONORS—THE BRITISH MEDICAL ASSOCIATION—THE PROFESSORSHIP OF MEDICINE AT OXFORD—DOCTORS AND THEIR FEES—A RIVAL TO LORENZ—THE GENERAL MEDICAL COUNCIL.

THE list of "honors" published yesterday on the occasion of the King's official birthday (his real birthday is November 9, but he chooses to have it celebrated on June 24, so as not to clash with the observance of "Lord Mayor's Day"), makes it pretty clear that if our gracious sovereign continues to occupy the throne for a few years longer a British subject who is not a "Sir" will be almost as rare as an American citizen who is not a "Colonel." The "fountain of honor" has played so freely that the newspapers have evidently found it difficult to discover at short notice who the new Knights and Baronets are. Not all whom the glittering water has sprinkled have been so thoughtful as one of the decorated persons who sent round to the newspaper offices a printed account of himself and his achievements. Among those whom the King has delighted to honor there are very few members of the medical profession. The most prominent of them are Dr. Thomas Stevenson, our best known toxicologist, and Dr. Constantine Holman, whose devoted work for the furtherance of the interests of the profession has long made him a conspicuous figure in the medical world. His business capacity and his tact in dealing with men have enabled him to save more than one of our medical charities from imminent ruin; to him it is mainly owing that Epsom College, which was little better than a fourth-rate charity school for the sons of men who had failed in the profession, has been transformed into a school giving an education as good as any to be got in this country, and rivaling in the number of academical distinctions won by its pupils the foremost schools of England. For half a century he was one of the leading spirits of the British Medical Association, which he helped to carry through more than one crisis. The reforming party, headed by Sir Victor Horsley, who for the last year or two has ruled the destiny of that body, looked upon Dr. Holman as the incarnation of the *ancien régime* and took the first opportunity of getting rid of him. Apart from this professionally insignificant faction, the distinction bestowed on Dr. Holman will be hailed with satisfaction by his brethren. The honor is all the more remarkable as the man on whom it it is conferred has never been anything but a general practitioner, a class on which the sun of royal favor very seldom shines.

The British Medical Association is to hold its annual meeting this year at Oxford. There seems to be every prospect of a successful gathering. The University will be in vacation at the end of July, when the pundits of British medicine will meet, but some of the official magnates will remain to do them honor and show them hospitality. Honorary degrees are to be conferred on some of the men of light and leading in the medical profession, and naturally there has been a difficulty in selecting the recipients. When the late Queen Victoria was about to celebrate one of her jubilees, the judges of the High Court met to draw up an address befitting

the occasion. The first draft made the oracles of the law describe themselves as "Conscious of their own unworthiness." This was objected to by those who had a proper sense of their own merit, and the late Lord Chief Justice Bowen suggested as an amendment, "Conscious as we are of each other's unworthiness." Doctors are not less conscious of each other's unworthiness than judges, and the authorities are having much trouble in deciding as to the claims of rival luminaries of medicine. The beauty of Oxford and the historical and other associations that make it almost a sacred place for Englishmen are sure to attract a number of members to the meeting. The arrangements are excellent. Each section is to have a college apportioned to its use, and the chief University buildings are set apart for the general meetings. The program of scientific work includes most of the questions that now agitate the medical mind, and the list of entertainments offers the assurance that members will find abundant opportunities of distraction after their serious labors.

The Regius Professorship of Medicine, which became vacant in the early part of the year through the resignation of Sir John Burdon-Sanderson, still awaits a new incumbent. The appointment is in the hands of the "Crown," that is to say, of the Prime Minister, Mr. Balfour. The explanation of the delay in filling up the chair is doubtless to be found in the conflict of opinion which is known to exist among the principal advisers of the Crown. There are two parties among those who have an interest in the medical school of Oxford: one composed mostly of physicians attached to London hospitals, who naturally are not anxious that the University should divert students from the schools with which they are connected; the other, eager to make Oxford a living school of medicine. The former wish the Professor to be a dignified figurehead; the latter desire to see the Chair of Medicine, which, as far as the teaching of medicine is concerned, is little better than a sham, converted into a chair of pathology, for the teaching of which Oxford offers abundant opportunities. It is the eternal battle of the new with the old. Which will conquer? The ideal solution would be that a chair of pathology should be adequately endowed, but at present the University has no funds available for the purpose. It is said that a wealthy person is prepared to play the part of pious founder by bequeathing a sufficient sum. But he is not yet dead and apparently has no immediate intention of going over to the majority.

An action at law tried within the last few days in the High Court of Justice throws a lurid light on the fierce struggle for life which is the lot of medical men practising in the poor districts of London. It was stated in evidence that there are doctors who will give advice and medicine for twopence, if the patient calls on them; if the doctor has to visit the patient the charge is fivepence! Sixpence a visit with medicine thrown in is a comparatively high fee. There are doctors who will attend a patient at his own home and supply him with physic for an inclusive charge of three shillings and sixpence a week. And these are not starving young doctors who, like a man whom I knew, keep themselves alive through the winter by drinking cod-liver oil in their own dispensaries, but prosperous traders who drive about in carriages. It is likely enough that the advice and the physic in many cases are together not worth more than the twopence at which the vendor values them, but the wonder remains how a man can make a living on such a scale of fees. Can it be wondered at that the medical profession does not stand very high in public opinion when its own members rate their services so low? The cause of this state of things can be expressed in one word—*overcrowding*. Congestion leads to overcompetition and this necessarily leads to what shopkeepers call "cutting." The question is an economic one which might be left to settle itself in accordance with the laws of the "dismal science." But political economy affords no remedy for the mischief done to an honorable profession by its degradation to the most ignoble of trades

While doctors strive to live on the wages of a crossing sweeper, there is a bonesetter in Scotland who is said to be making $500 a day. Some of the newspapers have suddenly discovered this modest philanthropist and are making it their business to spread his fame abroad. They vie with each other in sensational accounts of his performances with large headings like, "A Scottish Lourdes," "A Cripples' Mecca," and so forth. Never was bonesetter more trumpeted. Not Lorenz himself was more blatantly advertised, and one is almost tempted to see a nemesis in the fact that the Scotch bonesetter is declared to practice a "bloodless surgery" more successful than that by the Vienna professor. The newspapers give pictures of crowds of the lame and the halt besieging the shrine of the healer of cripples; but they do not give illustrations of the crooked backs on which he has operated, or of the dislocated bones which he has "put back into their place." The credulous scribes told off to recount the wonders worked by the "collier surgeon" differ widely as to his methods, but all agree that he has the "healing touch." They say nothing as to his failures and are careful to say little even of his successes; what they lay stress on is the number of deluded people who flock to him from a distance—for it is a curious fact that his own neighbors appear to have no belief in his thaumaturgic "touch"; and of the fees which he receives. Needless to say, no expert attestation of his wondrous "cures" is forthcoming. That, however, will doubtless be attributed to the jealousy of the doctors. It is a commonplace story. One only wonders with Mr. Crumples how these things get into the papers. The mention of bonesetting reminds me that one of the leading hierophants of the cult, "Professor" Atkinson, who died not long ago, has left only a trifle over $4,000. Yet he had an immense practice, not like his Scottish brother practioner, among poor people, but among the richest in the land. Some of the leaders in our surgical Israel did not disdain to meet him in consultation—of course privily and under seal, as Bobadil says. The profits of bonesetting would seem to be as unsubstantial as its "cures."

Sir William Turner, the President of the General Medical Council, will shortly resign that office. Till about two years ago he was Professor of Anatomy in the University of Edinburgh and he has now been elected principal of that seat of learning, a dignified post to which a considerable salary is attached. The honor of presiding over the deliberations of our Medical Parliament is a very barren one, and although Sir William Turner has ruled the assembly with a strong hand he has doubtless found the strain somewhat severe. The Council has managed to get at loggerheads with most of the Universities and Colleges in the three kingdoms. The London Colleges of Physicians and Surgeons openly defy its authority, and there is a growing feeling in the profession that the Council, as John Morley once said of the House of Lords, requires to be mended or ended. The choice of a successor to Sir William Turner will not be altogether easy. The names of Dr. Donald MacAlister, who represents the University of Cambridge, and Dr. Pye-Smith, who represents that of London, are mentioned. The former, who had a very brilliant academical record and who represents the largest medical

school in England, is an excellent man of business, and would make a tactful and efficient president; and the latter, who was for many years physician to Guy's Hospital, would fill the presidential chair with dignity. There is a possibility, however, that one of the representatives of Ireland may be chosen by way of saving the Council from an Irish grievance.

SOCIETY PROCEEDINGS.

THE SOCIETY FOR EXPERIMENTAL BIOLOGY AND MEDICINE.

Seventh Regular Meeting, held May 18, 1904.

The President, S. J. Meltzer, M.D., in the Chair.

Members Present.—Adler, Burton-Opitz, Dunham, Ewing, Gies, Jackson, Levene, Lusk, Meltzer, Murlin, Richards, Salant, Wadsworth, Wallace, Yatsu.

Members Elected.—P. B. Hawk, W. G. MacCallum, A. R. Mandel, R. M. Pearce, Franz Pfaff, William Salant, H. C. Williams, A. S. Warthin.

ABSTRACTS OF REPORTS ON ORIGINAL INVESTIGATIONS.[1]

The Lecithin Content of Fatty Extracts from the Kidney (preliminary report).—By E. K. Dunham. Rosenfeld has shown that the percentage of the alcohol-chloroform extracts from the dried kidneys of dogs, both normal and "fatty," fluctuates within very narrow limits. He calls these extracts "fat," and regards the microscopical examination as entirely untrustworthy for gauging the amount of fat in the kidney. His work on other organs has led him to the conclusion that, when the fat content is increased in the cells, it has been transported from the fat-depots of the body. It appeared to the author of interest to compare the extracts obtained from the kidney by Rosenfeld's method with similar extracts from the depot-fats. It was at once evident that they differed markedly in the percentage of phosphorus they contained, as is shown by the following analytic results:

Alcohol-chloroform Extracts.	Percentage of Phosphorus.
Human kidneys (mean of 28 analyses)	1.3849
Panniculus adiposis (4.2288 grams)	0.0026
Perinephritic Fat (5.6750 grams)	0.0069

The extract from the kidney contains from 200 to 500 times as much phosphorus as the extract from depot-fat. These facts suffice to show that the two extracts are not directly comparable and to throw doubt upon the idea advanced by Rosenfeld that the fat in "fatty" organs is a simple infiltration from the depots of the body.

The phosphorus in these extracts was found to be wholly organic in character. Protagon could not be detected even in 400 grams of the tissue. The quantity of jecorin that may have been present was too small to materially influence the analytical results. The most probable compounds containing the phosphorus are forms of lecithin. The barium hydroxide-platinic chloride method for the separation of cholin was employed with the following results:

	Extract. Grams.	Phosphorus. Percentage.	Platinum. Grams.	Lecithin in the Extract (Calculated as Distearyllecithin.) Percentage.
I.	0.4600	1.43	.....	37.23
	0.4600	1.47	.....	37.45
	1.5859	.....	0.0650	34.50
II.	0.6032	1.12	.....	29.11
	0.6032	1.11	.....	28.99
	2.1556	.....	0.0711	27.40

[1] Proceedings reported by the Secretary William J. Gies, Ph.D., of New York. The authors of the reports have furnished the abstracts. The secretary has made only a few abbreviations and minor alterations in them

Before incineration, in the first case, the platinum salt in the crucible weighed 0.2009 gm. The platinum, therefore, constituted 32.7 per cent. of the salt. Cholin platinic chloride contains 31.6 per cent. of platinum. It appears highly probable, however, that some of the platinum salt was decomposed during the concentration of its solution with heat. It is also possible that some of the cholin suffered decomposition, or was lost, in the manipulations preceding its precipitation with platinic chloride. With these considerations in mind, the foregoing results render it highly probable that the phosphorus is present in some form of lecithin, but, although these calculations are based on distearyllecithin, it is certain that this is not the only lecithin present. The fact that lecithin obtained in moderate purity (about 99 per cent.) from the kidney extract promptly blackens with osmic acid, indicates that the oleic acid radicle is present. The recognition of this fact would make but trifling changes in the calculations in this report. The foregoing analyses appear to justify the conclusion that one may, at least tentatively, assume the phosphorus content of the extracts obtained to be dependent upon the presence of some form of lecithin. Upon this assumption, the calculations given in the following table[1] are based:

	Extract. Percent. of Dry Organ.	Phosphorus. Percent. of the Extract.	Lecithin. Percent. of the Extract.	Lecithin. Percent. of Dry Organ.	Autopsy Report. Cause of Death.	Weight of Kidney. Grams.
			Human Kidneys.			
I.	11.42	2.11	55.07	6.29	Pneumonia and hepatic abscess	200
	12.48	2.00	52.03	6.49		
II.	11.44	1.35	35.14	4.02	Tuberculosis	200
XI.	15.40	1.18	30.84	4.76	Moderately fatty kidney	.....
	15.51	1.19	31.00	4.80		
			Beef Kidneys.			
II.	15.02	2.10	54.64	8.21	.....	.....
			Dog Kidneys.			
I.	14.93	2.04	53.29	7.95	.....	.....
			Rabbit Kidneys.			
I.	16.59	2.53	66.06	10.96[1]	.....	.....

[1] 2.24 per cent of the fresh kidney.

These analyses demonstrate that even in the kidney, which cannot be regarded as one of the fat-depots of the body and which probably plays little, if any, part in the general fat metabolism, the lecithin content must be taken into consideration in any study of the fatty extract. The limited number of the observations here referred to do not justify conclusions bearing upon the question of the nature of the fatty changes met with in the kidney, but it is the author's intention to continue the study of this subject.

On the Phloridzin Test in Bright's Disease.—By P. A. Levene and L. B. Stookey. Investigation of the action of phloridzin in Bright's disease has a theoretical as well as a practical interest. The mechanism of kidney diabetes is as yet imperfectly understood. The original idea that it was due to a change in the permeability of the kidney epithelium has gradually lost support, and instead there is a growing belief in the hypothesis that, in kidney diabetes, the sugar owes its origin to an exaggerated catabolic condition of the kidney. This view was first expressed by one of the authors in 1894. In support of this theory evidence was brought forward to show that in animals with injured kidneys phloridzin fails to bring about glycosuria, or causes it in less degree than in normal animals. However, it is impossible to injure, by means of drugs or by mechanical interference, only one special part of the kidney. In the course of Bright's disease there are known conditions under which the involvement of either the epithelium or of the glomeruli predominates to a very

[1] The author presented a large number of data. The table here given shows only a few examples of the many results obtained.

great extent, and this, of course, enables one to study the seat of the sugar formation within the kidney. The observations of most authors tend to show that when the epithelium of the kidney is injured, administration of phloridzin fails to cause glycosuria, or does so in very slight degree. The authors injected simultaneously phloridzin and methylene blue, and compared the course of the elimination of the dye with that of sugar. The results of their observations in a general way corroborate the statements made by other writers. In acute parenchymatous Bright's disease sugar fails to appear in the urine after the administration of phloridzin. In chronic forms of the disease, when only a trace of albumin can be detected in the urine, and when the permeability of the kidney for methylene blue is normal, there is frequently a diminished sugar elimination (diminished as compared with that in health after injection of phloridzin). In no case was there observed an impaired permeability for methylene blue with a normal sugar elimination, but the contrary was often the case. Levene's modification of Allihn's method was used for the sugar determinations. Further work in this direction is in progress.

Effect of Blood Serum in Pneumonia upon the Heart (Preliminary Report).—By Isaac Adler and Richard Weil. The object of these experiments was to determine whether blood serum in pneumonia has a specific effect upon the heart and, also, whether there is any difference in action between the serum taken *before* and the serum obtained *after* the crisis. The experiments were made upon the heart of the turtle, use of the mammalian heart being impracticable in this connection for many reasons. The fluids to be tested entered the heart through a glass cannula introduced through the right aorta into the corresponding ventricle, passed through the septum into the left ventricle and flowed out through a canula in the left aorta. Care was taken to keep the temperature, concentration and hydrostatic pressure uniformly constant. The veins were all carefully ligated. The small diaphragmatic vein at the apex was tied and cut, the ligature connected with a writing lever and the contractions of the heart thus recorded upon a drum.

Normal human serum acts upon the heart of the turtle as a violent inhibitor, but it was found that in a dilution of 1-20, or, better still, 1-15, it does not differ greatly in effect from "normal saline." All sera were thereupon tested in dilution of 1-20 or 1-15, and the routine of each experiment as ultimately adopted was as follows: Infusion into the heart, (*a*) "normal saline," (*b*) normal blood serum, (*c*) "normal saline," (*d*) serum before crisis, (*e*) "normal saline," (*f*) serum after crisis. In this manner after considerable preliminary experimentation very characteristic tracings were obtained.

Two cases of lobar pneumonia and one case of bronchopneumonia have thus far been studied. The tracings obtained were demonstrated and it appeared from them that the serum in pneumonia before the crisis, at least in the cases tested, acted upon the heart of the turtle as a most violent poison. The contractions at once became extremely weak and slow, and the pauses very long. The serum taken after the crisis gave tracings not very materially differing from those obtained with normal serum.

The Influence of Alcohol on Biliary Secretion.—By William Salant. In the author's experiments fasting or well-fed dogs were the subjects. Operation and collection were conducted in the usual manner. Ether narcosis was employed in every instance without previous injection of morphine. The rate of secretion was studied by comparing the amounts collected during periods of fifteen minutes. The rate of secretion during the first four or five periods was used as a control, at the end of which time alcohol was injected by means of a burette into the femoral vein. Varying strengths of alcohol were used, 4½ per cent., 30 per cent. and 60 per cent. The quantities administered were usually about 4 c.c. per kilo of body-weight.

After the injection of alcohol, it was found in all cases, that the secretion of bile continued to diminish, the diminution in the rate of secretion being, however, somewhat greater than in the two or three control periods immediately preceding the administration of alcohol. Since the much larger quantity of bile of the first and second periods probably represents bile that has been held back during the operation, it could not be considered as a control. The author therefore regarded as a control the rate of secretion during the following two or three periods. Whether this slightly diminished secretion is to be ascribed to the influence of alcohol can only be decided by further comparisons of the rate of secretion in alcoholized and normal animals. Thus, in three dogs without alcohol the rate of secretion corresponding to the alcohol periods was as follows: A decline during the fourth, fifth and sixth periods, succeeded by a rise in the next period. In the second experiment the rate of secretion remained practically steady during the fifth, sixth, seventh, and eighth periods. In the third experiment there was a variation but the average rate of secretion was about the same in the fifth, sixth, and seventh periods, as in the preceding two. It would seem therefore that the diminished secretion following the intravenous injection of alcohol might be due to the effect of alcohol.

A study of the effect of alcohol on biliary secretion after injection into the stomach was also begun. It would seem *a priori* in the light of recent investigations by Bayliss and Starling, Fleig, and Henriot, on the relation of secretin to the secretion of bile, that the author's method of administering alcohol ought to provoke secretion of bile. In the few experiments the author has made thus far he has observed that when 60 per cent. alcohol was introduced into the stomach there was a slight transitory increase of biliary secretion. With 30 per cent. alcohol, there was in some cases an increase, in some a decrease of the secretion of bile as compared with prealcoholic periods. At this stage of the work it would be premature to form any conclusion regarding this point. Whether this slight increase is due to increased gastric secretion and consequent formation of secretin or is reflex in nature will next be investigated.

The Influence of Repeated External Hemorrhages on the General Composition of the Blood.—By G. M. Meyer and W. J. Gies. Various observers have noted the fact that the composition of the blood changes after hemorrhage, but no systematic study has been made of these modifications. The authors have begun such an investigation for the purpose of establishing a more definite basis for comparative blood analysis. They reported the results of their observations on posthemorrhagic changes in the percentage content of water, total solids, organic solids and ash. Further study is in progress. Healthy, well-nourished or fasting dogs, in light morphine-atropine narcosis were used and quantities of blood ranging from 0.2 to 1.0 per cent. of body-weight were taken. These amounts were drawn from the femoral artery and approximately the same quantity was taken in each experiment at regular intervals, varying from fifteen minutes to two hours, until death ensued. In one experiment a continuous fatal hemorrhage was effected and the blood analyzed in portions. Thus far twenty experiments have been carried out.

In some of them the serum was also analyzed. The following conclusions were reported: Hemorrhage causes increase of water and decrease of solids in the remaining blood. *Hemorrhages of about 0.6 per cent. of body-weight* cause little or no change in general composition of the blood until after 2.5 per cent. has been taken. Under the conditions of these experiments it was generally found that the longer the intervals between withdrawals the less the maximal differences between composition of the first and last fractions. Short intervals between bleedings, all other conditions being equal, favored the largest total withdrawals before death ensued.

The differences in the serum ran parallel with those in the blood, but were less marked. The ash did not vary much in either the blood or serum, no matter how much blood was taken. The blood ash and that from the serum were practically the same in relative amount, though different in composition.

When *small* quantities of blood *equal to about 0.2 per cent. of body-weight* were removed at intervals of about a half-hour, little change was noted in either blood or serum until after 3 per cent. had been taken. After this quantity had been lost the changes following further hemorrhage were such as usually occur. The maximum differences in percentage composition of the first and last fractions varied somewhat. The differences in the amounts of solids, for example, ranged from 1.5 to 3.5 per cent. In *fasting animals* the influence of hemorrhage on chemical change in the remaining blood was somewhat more marked than in well nourished ones. The effect on the serum was about the same. Other influences in the experiments were carefully controlled. The observed effects were due only in slight degree to the narcotics and the conditions attending the operations.

Demonstration of a New Portable Sphygmomanometer.—By T. C. Janeway. Dr. Janeway's instrument was designed with the object of securing a thoroughly portable clinical sphygmomanometer, in which nothing essential to accuracy should be sacrificed. It employs the method of circular compression of Riva-Rocci and Hill, with the 12 cm. width of armlet proved necessary by Von Recklinghausen. The special construction of the cuff allows of adaptation to arms from 15 to 34 cm. in circumference. The original feature of the instrument is the folding U-tube manometer. This is a jointed U tube manometer (copied from Cook) fastened to the under surface of the box-lid, so arranged that, when closed for carrying, it measures 10¼ x4⅝x1⅞ ins., and, with armlet and inflator, weighs 2½ lbs. The manometer is perfectly secure when closed and stands firmly when open. The tube-caliber is 3 mm. The sliding scale is empirically graduated for each instrument, to compensate for variations in the glass tubing, and is accurate. All connections are of heavy pressure tubing. For inflation a Politzer bag is used, as by Erlanger, except that one with valve is necessary to fill the large armlet. The gradual release of pressure is provided for by a stop-cock, with needle-valve of special construction, the work of Mr. Charles E. Dressler, who is making the sphygmomanometer for sale. The method of use, as of the other modern sphygmomanometers, is based on the criterion of the return of the pulse after obliteration (Vierordt), for systolic pressure, and is similar to the Riva-Rocci and its modifications. A fair approximation of diastolic pressure may also be obtained in most cases, using the criterion of maximum pulsation (Marey, Mossi). This is especially useful in cases of aortic insufficiency, or marked hypertension. For experimental work upon the systolic and diastolic pressures, it cannot compare with Erlanger's more elaborate and costly instrument, but aims to serve the clinician by providing him with an accurate, yet not bulky or expensive apparatus for general use. Stanton's sphygmomanometer, which appeared after this one had been begun, answers the same purposes. The only criticism to be made of it is that 8 cm. width of armpiece does not afford a guarantee of complete accuracy on arms that are large and excessively fat.

Demonstration of Cytological Preparations.—By Naohidé Yatsu. Mr. Yatsu exhibited seven preparations, demonstrating important cytological structures found both in eggs normally fertilized and in those treated chemically. He spoke on the achromatic figure in mitosis, with special reference to the morphology and cycle of the centrosome.

Preparation No. 1.—Metaphase of the first polar mitosis with two centrioles at each pole (egg of *Cerebratulus*).

Preparation No. 2.—Sperm nucleus with sperm aster, in which each daughter centriole has acquired a new system of rays (egg of *Cerebratulus*).

Preparation No. 3.—Anaphase of the first cleavage mitosis, showing two centrioles in each centrosome (egg of *Cerebratulus*).

Preparation No. 4.—Telophase of the first cleavage mitosis, showing typical centrosomes (egg of *Ascaris*, Prof. Wilson's preparation).

Preparation No. 5.—Mitosis without chromosomes in a late blastula (egg of *Asterias*, unfertilized and etherized). In one of the blastomeres the aster is dividing forming a typical central spindle but devoid of chromosomes.

Preparation No. 6—Cytasters (egg of *Asterias*, unfertilized and etherized). Many cytasters are found in the cytoplasm, some dividing, some forming synthetic triasters.

Preparation No. 7.—Cytasters (egg of *Cerebratulus*, unfertilized and treated with a solution of calcium chloride). Many cytasters have appeared, the first polar mitosis being disturbed.

The Influence of Subcutaneous Injections, and of Instillations, of Adrenalin upon the Pupils of Frogs, with Demonstrations.—By S. J. Meltzer and Clara Meltzer Auer. Many observers have established the fact that subcutaneous injections as well as instillations of adrenalin exert no influence upon the width of the pupil in normal mammals. In a series of experiments published recently by the authors of this report it was shown that from twenty-four to forty-eight hours after the removal of the superior cervical ganglion a subcutaneous injection or an instillation of adrenalin caused a considerable dilatation of the pupil, which lasted an hour and longer. In the present communication the authors report that in frogs a subcutaneous injection or an instillation of adrenalin into the conjunctival sac causes an unmistakable dilation of the pupils of a normal animal. The dilation lasts a good deal longer than was ever observed in mammals even after removal of the ganglion; after instillation some dilatation may be perceptible as long as thirty-six hours. The maximum dilatation may even continue as long as twelve hours after injection.

When the cord is severed just below the medulla oblongata the pupils usually become small and ellipsoid in shape. A subcutaneous injection causes them to become wide and round. Instillation has the same effect. Finally the effect of instillation can be well observed also on the excised eyes, even when the adrenalin is applied some hours after excision, provided the eyes are kept moist. The experiments were demonstrated by Dr. Meltzer.

THE GERMAN SURGICAL SOCIETY.

Thirty-third Congress, held in Berlin, April 6 to 9, 1904.

Suture in Arterio-venous Aneurism.—Körte demonstrated a case of arterio-venous aneurism which had disappeared completely after a vessel suture. Franz has observed a similar case and conducted some experiments which show that the arterial blood may extend into the vein far beyond the knee joint, when the popliteal vessels are affected.

Action of Fluoride of Sodium on Bone.—By feeding young dogs with fluoride of sodium, v. Stubenrauch was able to induce a typical early caries of the teeth, great porosity of the bones of the extremities, but no retardation of growth. In very young rabbits there was retarded growth, caries of the teeth and necrosis of the jaw. As soon as the administration was stopped, the pathological process came to an end.

Carcinoma by Implantation.—According to Petersen, carcinoma cells may become separated from the mother tumor and start a new growth after short or long-continued contact with serous or epithelial surfaces or wounds. A close microscopical examination will often, however, show that inoculation does not take place but that the cells are carried to their new location by retrograde lymphatic transport. Epithelial inoculation is very rare in the same person and still more so from one individual to another. The slow or rapid recurrence of carcinoma is determined by the variety and malignancy of the primary tumor. Jordan has observed a case of recurrence after extirpation of the tongue for carcinoma after 19 years. In another case of mammary carcinoma, a nodule formed 15 years after amputation.

Pneumatic Chamber for Intrathoracic Operations.—The chamber constructed by Sauerbruch enables the operator to overcome the difference between intrabronchial and intrapleural pressure. An attempt was also made to equalize the pressure by increasing the pressure in the air-passages. Thus in animals, the lungs may be inflated from a bronchus and the bronchus then tied off; if the thorax be then opened, the lung will not collapse and a pneumothorax will not set in. For man this procedure is too radical and has not yet been tried, but it is invaluable in physiological experiment. Von Mikulicz emphasizes the ease with which extensive thoracotomies may be performed in the chamber and believes that difficult operations on the heart and intrathoracic esophagus will now be possible. The results on animals were very gratifying, but one patient died of cardiac collapse. The necessary minus pressure should correspond to 12 millimeters mercury. Brauer objects to the cumbersome and expensive chamber of Sauerbruch and has constructed a small box, holding no more than ½-¼ cubic meters of air, which he thinks is equally efficient. The head of the patient to be operated is brought into the box while the anesthetist introduces his hands through rubber cuffs. With the aid of a special apparatus, anesthesia can easily be induced. Petersen has seen animals revive immediately after pulmonary and cardiac collapse, when the pneumatic chamber was employed. The frequent repetition of the experiment seems to be an intense cardiac stimulant. He was able to remove a strip of lung tissue, the seat of a malignant growth starting from the spine, with perfect success, but when the dressing was changed without the pneumatic chamber, pneumothorax and death resulted.

Experiences with Cardiolysis.—During the last year, v. Beck has performed cardiolysis three times with good result. In one case, ascites, congestion of the liver and of the spleen, disappeared after resection of the 4th, 5th and 6th ribs and the boy was discharged absolutely cured. However, his condition during the first three days after operation was miserable. In the two other cases, the pericarditis had also developed after pleurisy and retraction of the thoracic walls was pronounced. It is necessary to remove the periosteum very freely so that the ribs will not reform.

Röntgen Therapy in Carcinoma.—That Röntgen rays have a beneficial influence upon neoplasms is unquestionable, for Perthes reports 12 cures in 13 cases of epithelioma. One carcinoma of the lip was cured after a single sitting of 25 minutes. Growths seated deeper than two-thirds centimeters are not influenced, however. The specific action seems to manifest itself in a cessation of cell-division; this can be experimentally demonstrated on ova or plant cells. Lassar believes that the best results in cancroids are obtained by combining Röntgen therapy with the use of arsenic.

Five New Operations on Liver and Gall-Ducts.—Kehr reports one case of apparent stone in the cysticus which turned out to be an aneurism of the hepatic artery. The sac was extirpated without the development of necrosis in the liver. The old opinion, that the hepatic artery should not be touched surgically, is thus no longer tenable. The second case concerns a tumor of the common and hepatic ducts. Both ducts were resected and the stump of the hepatic duct then fixed to the duodenum. This is the first case of resection of the common duct on record. In the third case hepatico-cholangio-enterostomy was done but the patient died after several weeks. In the fourth case a defect in the duodenum resulted which necessitated complete division of the duodenum, suture of the divided ends and gastro-enterostomy. A fistulous tract resulting from a retention cyst of the pancreas was implanted into the gall-bladder in the last case, and this followed by a gastrocystotomy. The pancreatic juice was well tolerated by the stomach.

New Formation of Gall-Bladder.—Seven months after the gall-bladder had been extirpated in animals, a new-formed reservoir was found by Haberer at the site where the cystic duct was ligated. When the cystic duct was also resected, the hepatic duct formed a slight dilation.

Removal of Stones in the Choledochus.—Kraske emphasizes the difficulties of choledochotomy, especially if the stone is situated in the intestinal end of the duct. It is especially hard to push the stone toward the liver and too energetic efforts may lead to injury and necrosis of the duct or the intestine. A case of this kind observed by the speaker died of inanition five weeks after the operation. It is often better to mobilize the duodenum and incise it. Injuries to the pancreas should be avoided though they are not always dangerous. The pancreas may, however, cause considerable trouble if the stone is situated in the diverticulum of Vater. In a case of this kind the choledochus was divided close to its entrance at the duodenum, to enable the extraction of a large stone. The sutures held for three days; after that the pancreatic juice was excreted in such large amounts that the patient died of inanition. It is questionable whether an accident of this kind can be prevented by drainage of the pancreatic duct; at any rate, drainage from the choledochus without opening the duodenum is simply impossible. In stones of the choledochus, Riedel makes a very large incision from the lower end of the sternum to below the navel. This enables him to pull forward a large portion of the liver and thus gives ready access to the deeper structures. Rehn believes there is a condition which closely simulates aneurism of the hepatic artery; he refers to hemorrhagic infiltration of the gall-bladder. Kausch warns against duodenal incisions and prefers to open the hepaticus, since if the suture does not hold here, the worst accident is a biliary fistula, whereas with a leak from

the duodenum the patient generally dies. The incision of Riedel is not to be recommended, on account of subsequent hernias; an incision following the course of the nerves is to be preferred. Kehr prefers the transduodenal route; he has had only two deaths among 20 cases. If the tampon is introduced some distance from the duodenal wound, there is little danger of decubitus. If the retroduodenal route is chosen, phlegmons are liable to develop.

Injuries of the Hypophysis.—Injury to the pituitary body may be expected after fractures of the base of the skull running through the sella turcica, with foreign bodies which penetrate the hard palate and skull from the mouth and after injuries, gun-shot or stab wounds which start from the convexity. Since most of these cases are fatal, little is known of the symptomatology. Madelung observed a girl nine years old who had been shot in the head; there were unilateral amaurosis, the remains of hemiplegia and an enormous adiposity. The course of the bullet was such that the hypophysis or its surroundings were probably injured.

Stolper remembers a case of pronounced acromegaly after severe fall upon the back of the head. At the autopsy the hypophysis was considerably enlarged and edematous and a metastasis was encountered in the right occipital lobe. Benda thinks that acromegaly is seen more often with hyperplasia of the gland than with a degeneration such as one would expect after a trauma. Experiments on extirpation of the hypophysis conducted by v. Eiselsberg were all unsuccessful, since the animals died soon after operation.

Psychical Disturbances with Abscess of Temporal Lobe.—In a case of temporal brain abscess, Borchard noticed severe psychical disturbances of a sexual nature. After incising the abscess, the symptoms disappeared.

Bone Suture in Subcutaneous Fractures.—In fractures of the elbow-joint and of the head of the radius, where the broken ends were not in apposition, König warmly advocated bone-suture. This also applies to multiple fractures of the same bone, to certain fractures of the neck of the femur which usually do not heal by bony union. In the latter an accurate suture of the capsule and soft parts is also necessary. This operation will be followed by good results even in advanced age.

Osteoplastic Repair of the Entire Diaphysis.—In a young girl, the entire diaphysis of the femur was removed for myelosarcoma. Friedrich replaced the defect by a portion of the tibia of an older child and achieved excellent functional results. In another similar case, the femur of a patient who had died of cancer of the stomach, was implanted with equal success. The implanted bone merely acts as a framework, permitting the newformed osseus tissue from the epiphysis to grow in the proper direction. The bone need not always be fresh but should be thoroughly boiled out and kept in sterile saline solution.

Early Operation in Renal Tuberculosis.—In forty-eight cases operated on by Kümmel, a primary focus was generally discovered somewhere in the body. In vesical tuberculosis a kidney was found diseased and removal of this organ cured the bladder condition. In the early stage, there are neither subjective nor objective symptoms, especially no pain or tumor, but at most a slight cystitis with turbid urine. The diagnosis is here made by ureteral catheterization. Every cystitis in the female is suspicious of tuberculosis if trauma and catheterization can be ruled out. The use of methylene blue injections as an aid to diagnosis is a valuable addition. It is a mistake to consider the modern methods of functional diagnosis as superfluous and difficult. Kronlein gives a report of 51 cases which constituted 30 per cent. of all his renal cases. The female is more predisposed owing to the frequency of cystitis and retention in the real pelvis. Seventy-two per cent. occurred in the third and fourth decade and in 92 per cent. the disease was unilateral. Functional renal diagnosis, though a valuable aid, does not always disclose the condition of the second kidney. Nephrotomy or resection is rarely sufficient; in most instances a nephrotomy is the only operation which gives hopes of permanent cure. Several classes of cases are recognized, such as suppurative and caseous tuberculosis, the diffuse form, the tuberous variety with unfavorable prognosis, and lastly the emholic form. In the latter the diagnosis can sometimes be made, as in the case of a tuberculous man, who suddenly experienced severe pains in the kidney region, gradually increasing in intensity. The speaker believes with others, that all cases of renal tuberculosis are hematogenous in origin. In the 34 cases, the kidneys were affected alone in 12; the lungs were diseased nine times, the bladder twelve times, a joint nine times and four times the entire urogenital apparatus. Twenty-four cases survived the operation longer than eight months; of the remainder, tuberculous lesions in the other kidney were found in only three.

New Operation for Chronic Nephritis.—The weak point of Edebohl's operation lies according to Babes in the reposition of the denuded organ into its non-vascular, fatty capsule, so that the chances for collateral circulation are very poor. The following methods have been tried on animals and are recommended as superior: 1. Covering the decorticated organ with omentum. 2. Intraperitoneal dislocation. The first method was tried once in the operating room but unfortunately the patient succumbed to a pneumonia.

Experience with Decortication.—P. Rosenstein, of Israel's clinic, thinks that Edebohl's operation is not only without result but actually dangerous in severe cases of nephritis. Edebohl's statistics do not bear severe criticism and his unilateral cases are certainly not unilateral. Israel himself has never seen a permanent cure. Stern, Riedel, Kümmel and Franke have had the same experience.

Increasing the Resistance of the Peritoneum Against Infection.—There seems little doubt that by increasing the number of leucocytes, a higher resistance on the part of the peritoneum against infections can be obtained. Von Mikulicz therefore injects a two per cent. solution of nucleic acid twelve hours before the operation since a hypoleucocytosis precedes the hyperleucocytosis. The course of the disease after operation seemed more favorable than without injection. The leucocytes are also increased by thoroughly flushing out the peritoneal cavity with a hot saline solution—a method which is certainly preferable to the dry way of operating.

Pathogenicity of Intestinal Contents.—Brunner finds that the contents of the lower portion of the gut are much more infectious than the upper and the contents of the vermiform appendix seem to be especially virulent. In the majority of cases the streptococcus was found.

Position for Peritonitis.—In purulent peritonitis, Küster rests his patients with a roll under the chest and pelvis and a support for the head, so that the arms remain freely movable.

Subcutaneous Feeding in Surgery.—In inflammatory processes of the peritoneum and in protracted vomiting it is often impossible to feed the patient in the normal way and subcutaneous feeding, if efficient, would be life-saving. Friedrich has had excellent results with sterilized olive oil up to 100 grammes daily and with 40 to 100 grammes of glucose in three to five per cent.

solution. A higher concentration is not deemed advisible since the injections are very painful and the solutions are no longer isotonic with the blood. Recently, various proteids were again tried. Only an absolutely pure pepsin-peptone seemed serviceable since it did not affect pulse, temperature or blood pressure and in doses of 20 grammes daily, did not appear in the urine. It is the best injected in seven per cent. solution, combined with salt and glucose. Many cases of peritonitis, gastric and intestinal perforation could be tided over the critical period by means of these injections.

Volvulus in the Stomach.—It is hardly recognized that the stomach may undergo torsion like the intestines. Borchard even speaks of two varieties: intracolic volvulus, where the colon participates, and supracolic volvulus, where the stomach alone is affected. Suggestive signs are meteorism involving only the epigastrium, singultus and negative result after examining with sounds. The therapy is very simple: the stomach must be brought back into the normal position, after its volume has been reduced by incision.

Glycogen Reaction of Leucocytes.—The demonstration of glycogen granules in leucocytes by means of the iodine reaction seems to have no diagnostic value except in tuberculosis where the pure forms can be easily distinguished from the mixed infections. However, Küttner thinks that the prognosis may be regarded as very poor if the reaction is strong, even where the number of leucocytes is not above normal.

Proper Time to Operate for Appendicitis.—Karewski believes that all cases of acute appendicitis result from chronic processes which have been going on in the interior of the appendix for a long time. Operation is indicated in all cases in which a chronic intestinal catarrh is in all probability of appendicular origin and internal treatment does not cure. The first acute attack also calls for the knife, since one can never know how long the process has been going on.

Bladder Trouble in Anilin-Workers.—The great frequency of tumors of the bladder is pointed out by Rehn. Twenty-one cases have come under his observation since 1895, of these three were benign and eighteen malignant. The patients had been employed in the factory from five to twenty-nine years. The prognosis is very unfavorable.

Treatment of Hernias.—In many hernias the relation of parts is so disturbed that it is absolutely impossible to bring the intestines back into the abdomen without prolonging the operation and seriously endangering the patient's life. Madelung thinks that the only remedy in these cases is a fecal fistula with exclusion of small or large pieces of the intestines. In small hernias in children and in adults who refuse radical operation Brodnitz has often seen good results from injections of alcohol.

Ileus of Syphilitic Origin.—Borchard reports a rare case of intestinal obstruction caused by a recent syphilitic tumor at the splenic flexure. The affection was recognized as specific during the operation so that an artificial anus was made and the patient subjected to antiluetic treatment. The cure was perfect and the patient is now free from symptoms.

Cancer of the Stomach and Rectum.—A pathological examination of cancers of the stomach and rectum should always be ordered even when the question of malignancy has been settled, since certain types will always recur, while others will give a fair chance of cure. Petersen then discusses the way these growths extend into the surrounding tissues; in the stomach the lesser curvature is most often affected but the duodenum is by no means immune since its beginning was found involved in no less than 30 per cent. In recurrences, the stomach plays the most imporant part, since recurrences from glands are less common. The opposite holds in the rectum where recurrences are most common in the cellular tissue and the regional glands.

JOHNS HOPKINS HOSPITAL MEDICAL SOCIETY

Regular Meeting held May 16, 1904.

Blood in Pregnancy.—Some recent work on the blood in pregnancy, done in the obstetrical ward of the Johns Hopkins Hospital, was reported by Dr. Thompson. The subject has received a good deal of attention, since the time of Morgagni, but the attention has been confined largely to fruitless discussion. Three conditions have been reported as found; either (1) no change; (2) an increase in the red blood cells and diminution of the hemoglobin; or (3) an increase in hemoglobin and diminution in the red blood cells. Many also have held that the blood condition depends on the general condition and not on the presence of pregnancy. A leucocytosis has often been observed and has been explained as due to a local irritation—a higher count having been found in the blood from the cervix than in that from the thumb. Virchow thought a change in the pelvic lymphatics probably explained the phenomenon, and other observers have connected it with the breast changes where a round-cell infiltration occurs. A fall in specific gravity corresponding to the drop in red blood cells has also been observed. The twelve cases studied and here reported were all negroes but one. All were well and were kept on the same diet. They were followed from October, 1903, to May, 1904, each being examined completely once a month. The red cells were found to be high at the extremes of pregnancy—and an irregular rise as pregnancy comes on was noted. The hemoglobin was low until the seventh month, but at the ninth month averaged 85 per cent. There was a slight absolute leucocytosis, the average count being 9,000. Ehrlich's stain showed practically normal proportions of the different species of leucocytes. The specific gravity was found to be high early in pregnancy, diminishing later, again to rise toward the end. Possibly the changes in the water output, pointed out by Slemmons, may explain this phenomenon. Dr. Emerson, in complimenting the author of this paper on his results, said that what was needed in blood work was not a study of many cases but of a few cases carefully observed and Dr. Thompson's work on the specific gravity of the blood was of particular interest.

Benign Bone Cyst.—Dr. Halsted reported a case of benign bone cyst. The patient, a boy of seven years, had had a fall five years before admission, which had rendered him unconscious and "broken" his left thigh below the trochanter. Three weeks afterward he was walking with a crutch. Some time later the leg was wrenched, the thigh became swollen at its middle, and motion became impaired. There was no crepitus, false motion, or tenderness. Skiagraph showed a swelling reaching up to the head of the femur, having the characteristics of a cyst. Operation was done and a cyst filled with brownish fluid found. The new growth invaded the medullary canal, but was evidently benign and the leg was not amputated, the tumor being excised and the head of the bone enucleated. Pathological examination showed the specimen to contain a good deal of cartilage with several small and one large cyst. Strictly, it was a fibroma though microscopically it looked a good deal like a sarcoma. Islands of misplaced cartilage, as Virchow said, often produce cysts; and if it is remem-

bered how active resorption is in the young the origin of such a tumor is easy to understand.

Gastrectomy.—Dr. Bloodgood reported an operation of this kind, done for an early ulcer or cancer. The patient, a man of thirty years, complained of pain in the epigastrium not confined to one side or the other, but situated in the middle portions and about under the ensiform. There was no rigidity, muscle spasm or tenderness. Operation was done, some inflammatory infiltration of the omental fat found, enlarged glands palpated on the the lesser curvature and a gastrectomy by Billroth's first method done. Recovery was uneventful and the patient is now well. The specimen showed an ulcerated patch on the stomach wall. Dr. Bloodgood said that the statistics of the surgery of carcinoma of the stomach showed conclusively that the cases must be seen earlier if anything is to be accomplished.

Dr. Halsted reported a similar case on which he had recently operated. In this case there was an ulcer palpable through the abdominal wall and the patient had been shown to the students as a most typical case of gastric ulcer. At operation enlarged glands were found on the greater curvature and these were, on section, carcinomatous. Gastrectomy for cancer was done by Billroth's second method. The man is now well, his weight has increased 30 pounds and he eats everything. Dr. Emerson, referring to the chemistry of the gastric secretion in early cases of cancer, said that when a cancer grows on an ulcer the hydrochloric acid varies greatly in amount from day to day, and this fact may be of assistance in early cases.

Pulmonary Distomiasis.—Dr. Emerson, referring to the specimens which he exhibited of the first case of pulmonary distomiasis to be reported in this country, gave a slight account of this condition. The disease occurs with great frequency in Japan, Formosa and elsewhere. The chief, if not the only, symptom is hemoptysis with final death from anemia. Between the hemorrhages the sputum remains rusty. This case shows the value of fresh sputum examination.

MEDICAL AND CHIRURGICAL SOCIETY OF MARYLAND.

Stated Meeting, held May 20, 1904.

Skin Lesions.—Dr. Carey Gamble showed a patient exhibiting skin lesions in connection with visceral crises. The patient was a German, forty-seven years old, who had had smallpox when twelve years of age; no rheumatism and an otherwise negative past and family history. He had, however, had between his ninth and his eighteenth years several attacks characterized by great abdominal pain, distention, vomiting and delirium. The pain usually lasted for four weeks and the delirium occurred on and off during that time. There were no skin eruptions. At eighteen he entered the army and since then had had no illness up to admission except a left-sided pneumonia in 1901. In April he was taken with a dry cough, pain in the right chest and swelling of the right arm. A hemorrhagic rash appeared over the body, there were suppression of the breath sounds, a few râles and kodiac resonance in the right axillary line. Urine was negative. A little later he was taken with great pain in arm and shoulders, vomiting and epigastric pain. The gums became spongy, there was distention of the right side of the abdomen and the patient lost perfect control of the bladder. Albumin, casts and some blood appeared in the urine. There were pains over the heart. The hemorrhagic spots in the back became necrotic and sloughed out, leaving areas of ulceration. The onset of this case was much like appendicitis, but an exploratory operation was not done since the rash had previously appeared, and because the patient was weak and of an obvious hemorrhagic diathesis surgical treatment was thought unwise. The condition present was that described recently by Osler, who called attention to the group of cases characterized by skin lesions in association with visceral crises.

Dysentery.—Dr. Knox reported a study of 110 cases of dysentery seen at the Mount Wilson Sanitarium. He called attention to the various theories which have been advanced to explain this disease and emphasized the absolutely fanciful nature of "miasms," "summer flukes" and "infectious states of the atmosphere," etc. More accurate knowledge of summer diarrhea has led to a more rational treatment; but the results of Shiga's serum at the Mount Wilson Sanitarium, though not absolutely negative, have been disappointing and prophylaxis seems to offer most. Of the cases studied 83 were under one year and only six over two years old. Most of the cases occurred in July and there was always a sudden increase after a period of excessive heat. Ten per cent. of the children were breast-fed and 24 per cent. had taken condensed milk—significant figures from the standpoint of etiology. The hygienic surroundings of none were ideal. In only four cases were there other children with the disease in the same house. The dysentery bacillus, though never isolated from water, may be carried by it just as the typhoid bacillus which, though impossible to find in water, is carried in that way. Many of the breast-fed and condensed-milk-fed babies in this series had been given unboiled water, and this may have been the source of the infection. The prognosis, as given by a study of the mortality of Dr. Knox's cases, is good after the first year, previous to which time practically all the deaths occur.

Posttyphoidal Psychoses.—Dr. Edsall read a paper on the posttyphoidal psychoses in children. He referred to the great vagueness in the literature as to this subject, the only comprehensive work attempted having been that done by Paris students for their theses. The frequency of this condition, the character of the psychosis and the prognosis are the points of especial interest. As to frequency, the idea among clinicians of its great rarity is an erroneous one—80 cases being easily found in the literature. As to character, it is commonly stated that it is a mania, but Dr. Edsall found in his 80 cases 40 of mania, 18 of dementia and 22 of melancholia. A girl of nine years in his practice with a severe typhoid and living on low diet because of hemorrhages developed delusions and symptoms of meningitis for which lumbar puncture was done. She recovered from the fever, but was left with a psychosis characterized by irrelevant fears, delusions of sight and hearing, exaggerated religious emotion, double personality. Her condition gradually improved. She is now quiet and reflective but otherwise well. As to prognosis, the clinicians usually say that the case will recover, the psychiatrists that it will not. In this series most of the melancholias got well, but 20 out of 65 cases remained persistently insane—the majority being demented. Dr. Edsall feeds his cases well whenever mental symptoms occur, as a prophylaxis against dangerous psychosis. Dr. Mitchell thought there might be some relation between the period of starvation and the incidence of insanity and suggested that studies in metabolism might throw some light on the condition. Possibly sex might be an etiological factor. He reported having seen hysterical attacks after typhoid (aphonia, paralysis, blindness, etc.).

Dr. Reuling said that dementia precox frequently

follows typhoid and every slight psychosis should be carefully watched.

Dr. Futcher called attention to the frequency of a neuropathic family history in the adult cases and suggested that this might be found also in children.

Dr. Edsall said that no relation could be shown between the severity of the disease and the incidence of a psychosis, and that more boys than girls are affected —contrary to what we should expect. The influence of heredity has not been carefully studied, but Morel reported a series of eight children from one family, all developing typhoid followed by persistent psychoses. Four of these were maniacal and four demented.

CHICAGO SURGICAL SOCIETY.

Stated Meeting held May 2, 1904.

Carcinoma of the Cheek.—Dr. Nicholas Senn reported a case of extensive carcinoma involving the left cheek, in the center of which was a perforation which communicated with the cavity of the mouth. Acting upon the supposition that it might be a case of abscess, he decided, first, to curettage, hoping to improve the local condition as well as giving an opportunity to make an early diagnosis by the aid of the microscope. Sections under the microscope showed it to be a case of unusually malignant form of carcinoma that had its starting-point somewhere about the alveolar process on the left side, involved the entire cheek, and gave rise to extensive destruction. There was extensive regional dissemination, although the disease had lasted only three months. A radical operation was resorted to. The entire cheek was removed, leaving the angle of the mouth and a small portion of the cutaneous covering of the cheek. He sacrificed the periosteal covering of the jaw on the corresponding side, and made regional dissection by removing the submaxillary gland with the chain of lymphatics, as a preliminary to excision of the cheek, and covered the enormous defect which was produced by a plastic operation, using Thiersch's skin grafts. The wound healed by primary intention throughout.

Multiple Tuberculous Abscesses.—Dr. Senn reported a case of tuberculosis of the ribs, of a most pronounced type, in a man of forty years of age. Three large tuberculous abscesses involved the left side of the chest. One of these ruptured spontaneously, and a fistulous opening communicated near the nipple with a very large abscess cavity. Another abscess was found at the junction of the ribs with the cartilage near the sternum, and another to the left of the mammary line. The third, fourth and fifth ribs were the seat of tuberculosis. The first abscess was the result of tuberculous perichondritis. The focus of tuberculosis of the fourth rib was almost directly over the pericardium close to the nipple. The third abscess was a little to the left and involved the fifth rib. The ribs were resected in their entirety, necessitating an extensive operation.

Acute Osteomyelitis.—Dr. Senn showed a patient for the purpose of making a few remarks in reference to the clinical behavior of certain forms of acute osteomyelitis.

Cysts of the Ductus Thyroglossus.—Dr. Senn had encountered three cases in two weeks of cysts of the ductus thyroglossus. The patients were all young subjects, eighteen to twenty-five years of age, two females and one male. The cysts were comparatively small. The largest one was about the size of a small walnut. They were located in the median line between the thyroid cartilage and the base of the hyoid bone. The enlargement was slow, accompanied by pain and swelling. The skin was movable over the surface of the swelling in all of the cases. Fluctuation was distinct. Complete excision was resorted to. The cyst wall in one of the cases was as thin as tissue paper.

Fibroma of the Periosteum.—In the last ten days Dr. Senn said he had encountered two cases of fibroma of the periosteum. In the first case the fibroma had its starting-point from the periosteum of the second rib close to the cartilage. The tumor extended over the surrounding bony framework in mushroom-like manner, and underneath the clavicle. The tumor was removed through a curved incision, with its convexity directed upward, and the flap reflected as far as the clavicle, thus laying bare freely the base of the tumor, which he found intimately attached to the periosteum of the second rib near the sternum. The tumor was very firm and smooth, and on making a section it cut almost like cartilage. He removed a second fibroma of the ribs last Friday from a woman thirty years of age, which was situated at the lower part of the scapula. The patient first noticed the tumor eighteen years ago. It became stationary, but later gave rise to serious functional disturbance by fixation of the arm. The tumor was removed.

Verruca Senilis.—Dr. Senn exhibited two specimens from the face of a woman, seventy-one years of age, the subject of multiple senile warts. In both cases the disease involved the malar prominence on both sides. There were a number of these warts scattered all over the face, those over the malar eminence being the seat of repeated irrigations, and had undergone transformation into epithelioma.

Myositis Ossificans.—Valuable as the X-ray is as a diagnostic resource, Dr. Senn said occasionally it leads physicians into difficulties. He related a case briefly in confirmation of the correctness of this assertion. The patient was a colleague upon whom he had operated twice before, once for a diffuse septic inflammation involving the right arm and forearm, and a second time for appendicitis. For a number of months he had complained of a vague pain in the right shoulder. The patient regarded it as a rheumatic affection. Local and general treatment failed to give relief. The pain increased in severity, and the shoulder-joint almost completely lost its function. Dr. Senn could find no indication of any swelling, but found at a point corresponding to about the middle of the base of the deltoid a limited area of tenderness. The X-ray picture showed in the center of the deltoid muscle a dark elongated spot. The shoulder-joint itself was normal. He thought he would make no mistake if he considered the case on the face of the photograph one of myositis ossificans. He thought the dark island represented bone tissue in the deltoid, as it appeared entirely separate from the greater tuberosity of the humerus. Upon this supposition he acted. He laid the deltoid muscle bare by a curved incision, reflected the flap upward, and found the deltoid absolutely normal. In palpating the deltoid he found at a point corresponding to the outer side of the bicipital groove of the greater tuberosity a hard swelling. He separated the deltoid vertically by the use of a director and came down to a hard mass, not bone, but underneath the periosteum it appeared to be encapsulated. He incised and exposed a large mass of inorganic salt-sodium biurate. Dr. Senn also reported two cases of lipoma arborescens. He also exhibited the new army splint devised by Howard W. Beale, and a combined stretcher and splint devised by Professor Stokes.

The Union of Ununited Fractures of the Neck of the Femur by Open Operation.—Dr. Leonard Freeman, of Denver, Colo., read a paper, by invitation, on this subject. He went at length into the literature of this subject, after which he reported a case of his own in a heavy, muscular man, thirty-two years of age, who had injured the right hip by falling on it in 1903. Pa-

tient was up on crutches in about four weeks, the extent of the injury not having been recognized. When he saw him on September 23, 1903, about four months after the injury, the patient was still unable to use the limb in walking, owing to pain in the hip and knee. There was shortening of two and a half inches, with a corresponding elevation of the trochanter, although this could easily be overcome by traction, the manipulation being accompanied by indistinct crepitus. Operation was performed October 10, 1903, about five months after the injury. Anterior longitudinal incision was made external to the sartorius, through which the neck of the femur was readily exposed, and the fracture located near the end of the bone. With difficulty a mass of tough fibrous tissue was snipped with scissors, between the ends of the fragments, which were freshened on each side of the gap with a chisel. A small incision was then made over the trochanter externally, and a hole for the reception of the screw drilled through the base of the trochanter, the external fragment of the neck, and into the head of the bone. The drilling proved to be a mere form, for the bones were so soft that the blunt screw could have been pushed directly through it without the boring of a preliminary hole. When the screw was in place, its outer end projected between the stitches used in closing the wound. Owing to the softness of the bone, the parts, although receiving considerable support, were far from being firmly held, so that it was possible to displace them with moderate force by rotating the limb or pushing it upward. On account of oozing, it was necessary to pack the wound with a strip of gauze, which was removed in a day or two, the opening closed, and primary union obtained. Extension, a long side splint, and a pad beneath the trochanter were employed. For several days the suffering was great, necessitating the constant use of morphine. In a week or so a little infection appeared about the opening through which projected the screw, which at the end of about two weeks caused a rise in temperature to nearly 100° F, accompanied by chills and much general disturbance. On removal of the screw these unfavorable symptoms promptly subsided, showing that they were probably due to infection of the cancellous structure rather than the joint. The subsequent recovery was rapid and uninterrupted. There was about one inch shortening. In the face of various tests, the union seemed to be sound and bony. He examined the patient again, a little over six months after the operation, and found the following condition: Union apparently firm, considerable callus, flexion to nearly a right angle, rotation almost normal, and about one and a half inch shortening. There was still enough pain in the joint anteriorly to prevent the patient discarding his crutches, although it was much less than before the operation, and was decreasing constantly. When not atempting to walk, the weight could be borne upon the limb with but little, if any, discomfort. Up to the present time the case had not been a complete success, the result being marked improvement only. What the ultimate outcome would be was yet to be ascertained.

Dr. Nicholas Senn questioned whether Dr. Freeman had reached an ideal result in his case. In the years 1882 and 1883, the speaker studied this question scientifically. Up to that time it was doubted whether union by bone under any circumstances could be obtained in cases of intracapsular fracture of the neck of the femur. He produced this fracture on the lower animals by drilling the neck of the femur in different directions and fracturing it, satisfying himself in each instance that he had produced a fracture inside the capsule. He treated twenty-three of the animals thus experimented upon by the methods then in vogue, but in all of these cases he failed. He then resorted to direct methods of fixation. Breaking the bone in a similar manner, he made use of ivory bone pegs and metallic nails. In ten experiments following the twenty-three failures he demonstrated that he had obtained bony union in nearly all of them. He found afterward that the same results in the human subject were obtainable by indirect methods of fixation by bringing the fractured surfaces in contact and holding them in apposition by lateral pressure by a splint of his own device. He had treated since that time fifteen or twenty cases, and in the majority of them could not only demonstrate excellent functional results, but union by bony consolidation.

Dr. Arthur Dean Bevan spoke of fracture of the neck of the humerus, and reported three cases upon which he had operated. In these he had made the open operation, wired the fragments, or had resected the head of the bone. He had one case of infection, which resulted in the loss of function of the shoulder-joint temporarily, and endangered the life of the patient for weeks. In the other two cases he obtained union by primary intention, and the results were satisfactory.

Dr. A. J. Ochsner had followed the method of treatment described by Dr. Ruth, in a paper read before the American Medical Association, in sixteen cases, two of which died. There was union in all of them. The amount of shortening in all of them was less than three centimeters. He had made the open operation in one case only of ununited fracture with painful hip. He used two Parkhill screws through the neck and the head, but the result was not satisfactory, as it was necessary suqsequently to remove the head.

Dr. Alexander Hugh Ferguson had treated three cases of ununited fractures of the head of the femur by the open operation with very good results.

Dr. Freeman, in closing, agreed with the speakers that in recent fracture of the neck of the femur the open operation should be avoided. He did not think there was as much danger attending the open operation from infection as Dr. Senn had intimated. Parkhill had used his clamp in fifteen or twenty cases without bad results. Infection, when it occurred, was along the tract of the screw into the cancellous tissue, and in his own case as soon as the screw was removed the infection subsided.

NORTHWEST MEDICAL SOCIETY OF PHILADELPHIA.

Stated Meeting, held April 26, 1904.

The President, Hugh Hanna, M.D., in the Chair.

Internal and External Hemorrhoids was the title of a paper read by Dr. Lewis H. Adler, Jr., in which he urged the necessity for careful ocular and digital examination of all cases suspicious of rectal trouble. He divided, external hemorrhoids into (1) venous, (2) cutaneous, and (3) compound. The first variety being again subdivided into three forms (*a*) a marked varicose condition of the plexus of the external hemorrhoidal veins; (*b*) a thrombosis of the plexus; and (*c*) a clot of extravasated blood due to rupture of a varicose vessel. The internal variety he considered under the forms of (1) varicose, (2) capillary, and (3) compound. In regard to the treatment of external hemorrhoids he noted the fact that it is usually only when the tumors are inflamed that the patient will seek medical advice, and believed the best method of treatment to be operative, if the patient will submit thereto, which may be accomplished (1) by excision, (2) by simple incision, and (3) by excision and primary suture of the cutaneous edges of the primary wound. He stated that excision was the method most frequently employed, which he described in detail, advising that

the hair be not shaven; and recommending the anesthetization of the tumor by a two per cent. solution of hydrochlorate of cocaine injected hypodermatically. Operation by simple incision was also fully considered and the chief objection thereto thought to be that the skin distention occasioned by the inflamed pile is left, and may subsequently become inflamed or refill with blood.

The advantage of simple excision and primary suture of the resulting wound has the advantage hope of obtaining primary union, but the author stated that he had abandoned it because of the liability of infection of the suture tracks, and because he believed the annoyance to be considerably increased by the mechanical presence of the sutures over what it was if the wound was left to heal by granulations. The palliative treatment consists of keeping the parts thoroughly clean by bathing with hot water and the application of soothing and astringent lotions during the inflammatory period, together with careful regulation of the bowels, diet and rest in bed. The treatment of internal hemorrhoids he divided into (*a*) preventive, (*b*) palliative and (*c*) operative. The capillary pile he believed could be best treated by the electrothermic cautery; while he believed that the nitric acid treatment was also worthy of mention. The preventive treatment consists to a large extent in the avoidance of sedentary habits, the use of improper toilet paper (such as newspaper, printer's ink being a decided irritant), excessive venery, improper diet; constipation, and the use of drastic purgative medicines. The palliative treatment should be with a view to (1) the reduction of any inflammation, (2) the arrest of hemorrhage, and (3) the prevention of prolapse of tumors. It includes the various details mentioned under preventive treatment, and in the early stages relief will often be produced by sponging the parts with cold water and in some instances an injection of cold or ice water after a stool. He also considered in detail the formula of Dr. S. G. Gant for the relief of inflamed hemorrhoids and that of Dr. James P. Tuttle for the relief of bleeding. He considered in detail the various operative procedures of divulsion, injection, ligature, clamp and cautery and Whitehead's, stating that he preferred the clamp and cautery method for the reasons that the patients suffer less pain; that recovery is quicker and that the constitutional effects are less.

Diagnosis and Treatment of Fistula in Ano.—This was the paper of Dr. J. Coles Brick, in which he referred to the fact that out of 16,060 treated in St. Mark's Hospital, London, between 1872 and 1891, a large number were of some form of fistula in ano. The consensus of opinion seems to be that fistula in ano is almost invariably secondary to abscess, although congenital cases may exist occasionally. He referred to the cases of this character reported by Dr. Kurt Bartholdy (*Arch. f. klin. Chir.*, LXVI., p. 956, 1902), and also described in detail three cases of suppurating dermoid cyst between the rectum and sacrum reported by Serein (*Med. Obosrenje*, January, 1901), causing this condition and the anorectal sinus of Hermann. As the great proportion of fistulas whose internal openings have been found are at the mucocutaneous junction, he believed a plausible cause to be injury by hard fecal masses to the delicate mucosa at this point and the possible introduction of septic micro-organisms into the lymphatics or Hermann's sinus and then conveyed into the ischiorectal fossa or in some cases higher up in the rectum. No sex or age is free from the disease, although the male during middle life is the most frequent sufferer. Allyngham reports that 14 per cent. of his cases of fistula were tuberculous, although many cases have been seen in which there was no indication of tuberculous ulcer. The primary influence of syphilis is through an ulcerative process. The writer referred to a case in which after curettment and packing of the fistulous tract, granulations did not form. The husband had a specific history and after giving specific treatment the wound began to be more pink, healthy granulations formed and it closed perfectly. He laid stress upon the importance of carefully deciding the etiology of the disease; whether tuberculous or specific, superficial or of deep origin. He referred to the general classification as complete and incomplete, internal and external, and described in detail the method of examination for each variety, laying particular stress upon the importance of a good light and recommending that the patient be placed in the Sim's position with the buttocks slightly elevated by means of a small pillow. Most patients dread such an examination and it should be done with as little pain as possible. A swab of cotton wet in a 10 per cent. to a 20 per cent. solution of cocaine should be introduced into the anus and allowed to remain there a short time, after which the index finger should be introduced and gradual dilatation accomplished. The treatment may be either palliative or operative; the palliative treatment rarely effecting a cure, but simply relieving the condition. In blind external fistula in which the pus is watery, it is the safest, but if there is much induration, burrowing will continue and the longer the fistula is left the more difficult it is to cure. He referred to the methods of Allyngham, who reports the cure of 17 cases by the use locally of strong solutions of carbolic acid and iodine or chromic acid. Matthews uses the fistulatome, by means of which the fistulous tract is scarified, but he nevertheless prefers the knife; and De Vevey, who uses tri-weekly injections of a 2 to 2½ per cent. of copper acetate solution, keeps the patient in a reclining position, and also administers guaiacol and small doses of copper acetate internally. Of the operative methods of procedure, excision is the most in use to-day, although elastic ligature, electrolysis and ecraseur all have their advocates. Whatever operation is done the patient should be carefully prepared therefor. Free catharsis should be had one and one-half to two days before the operation; a laxative pill should be given the night before and the patient put on a liquid diet. Early on the morning of the operation an enema of hot soapsuds should be given, in order to clear the file of operation from fecal matter. In cases of lung involvement ether should not be used. The bowels should be kept confined for five or six days after the operation, after which an enema of oxgall, glycerin and water may be given, if required. He laid especial stress upon the importance of after treatment, and the cases should be watched until all granulations have disappeared. When the bowels are to be confined for four or five days a rubber tube covered with gauze should be inserted in order to allow the escape of gas.

Dr. Andrew J. Downs stated that he favored the clamp and cautery operation, who stated that he had performed all the various methods for the removal of hemorrhoids, with the exception of the Whitehead operation, which he believed to be disadvantaged by the fact of its length and also by the fact that it was more apt to transmit infection; the operation which was less likely to cause the latter complication being the clamp and cautery, which he does by means of the electrothermic angiotribe, which instrument combined the simultaneous application of heat and pressure, the current being supplied either from a motor or storage battery. He described in detail the instrument and operation and stated that in the last three cases he had left

the button, of tissue, as it acted as an extra sealing, if there was any tendency for the ribband to open. He referred to two cases in which he had recently performed the operation, one case having previously had a difficult hysterectomy, and the other an operation for appendicitis, both of whom stated that they experienced no pain during the operation. The operation can be quickly performed, the speaker stating that he had frequently performed it in eight minutes. In reference to fistula, he believed that the sphincter should be preserved, if possible.

Dr. Wilmer Krusen referred to the importance of carefully examining into the pelvic conditions of women in whom operations for rectal conditions were performed, believing that in many instances the healing was interfered with by some pelvic condition, such as a retroflexed uterus or a pelvic tumor.

Dr. T. Turner Thomas referred to an article which had recently appeared in the *Boston Medical and Surgical Journal*, in which the writer reported 150 cases of the Whitehead operation with no deaths and with only five strictures, the time of the operation varying from five to twenty minutes, with an average of 12½ minutes.

Dr. C. Hershey Thomas reported three case of fistula without any internal opening, all of which healed up very nicely without making any.

Dr. Lewis H. Adler, Jr., in closing, stated that he believed the danger of stricture from cutting the sphincter was an overrated one; and that he had never had a single case of long continued incontinence in any case on which he had operated. He stated that he did not believe too strong solutions of cocaine should he used, as the absorptive powers of the rectum are very high, and that he always used a two per cent. solution. In regard to tuberculous fistula, he stated that there were many cases occurring in tuberculous subjects, in which the abscess was not tuberculous, and that from an investigation he had recently been making he believed that the instances of tuberculous abscess were quite limited. In any event he did not feel that it made much difference if an excision was done.

Dr. J. Coles Brick, in closing, emphasized the value of carefully looking into the pelvic condition, and both relieved if necessary. He believed that a suture inserted at the time of the operation was very valuable, if the patient was so situated that careful attention could be paid to him. In regard to the carbolic acid, he stated that it acted as a germicide and mild irritant. In regard to the use of cocaine, he referred to the case of a man who had by the urethral use of it been overcome; and that he never gave a stronger solution than two per cent. by injection and usually one-half.

BOOK REVIEWS.

The Summer Diarrheas of Infants, Their Etiology, Pathology and Treatment. By H. Illoway, M.D. E. R. Pelton, New York.

Dr. Illoway's little book is likely to be of special service during the heated term, because it insists on the fact that the predisposition to the infectious conditions known as summer diarrheas is really a form of themic fever consequent upon the lack of resistance of the child to continued high temperatures. His very practical suggestion is that children should be kept cool by bathing, by the removal of clothing and as far as possible by keeping them out in the open air but in the shade. Other features of summer diarrheas are also suggestively touched, and the book will be useful for those who have many city children to care for during the hot weather.

Tuberculosis and Acute General Military Tuberculosis. By Dr. G. Cornet, of Berlin. Edited, with additions, by Walter James, M.D., Professor of the Practice of Medicine in the College of Physicians and Surgeons (Columbia University), New York. W. B. Saunders & Company, Philadelphia, New York, London.

There is probably no more complete treatise on the general subject of tuberculosis in any language and certainly none in English anything like as complete and so thoroughly up to date as this volume of the Nothnagel series. Professor Cornet's work has well been called exhaustive. The American editor has added not a little of value from the recent literature to what was already an extremely satisfactory treatment of an extensive and difficult subject. Besides new material has been incorporated from some recent standpoints with regard to tuberculosis. For instance, the chemistry of the tubercle bacillus and of changes of media which favor its growth have in recent years occupied much attention and this subject is treated very fully in this volume by Dr. E. R. Baldwin, of Saranac Lake.

At the present time tuberculosis has come to occupy a very prominent place in the mind of the general practitioner of medicine. This is mainly due to the fact that the disease is no longer considered either hereditary and therefore not preventable nor necessarily fatal and therefore hopeless of treatment.

In the present volume the long chapters on the prophylaxis and the therapy of pulmonary tuberculosis are full of practical suggestions that cannot fail to be of the greatest help. Everything new and old has been discussed in the matter of treatment and the conclusion lies in favor of the open air, abundant diet regime shown to be the only rational basis for successful phthisiotherapy.

BOOKS RECEIVED.

International Clinics. Fourteenth series. Volume I. Edited by A. O. J. Kelly. 304 pages. Illustrated. J. B. Lippincott & Co., Philadelphia.

Materia Medica for Nurses. By Emily A. M. Stoney. Second edition. 12mo, 300 pages. W. B. Saunders & Co., Philadelphia, New York and London.

Epilepsy and Its Treatment. By Dr. Wm. P. Spratling. 8vo, 522 pages. Illustrated. W. B. Saunders & Co., Philadelphia, New York and London.

Progressive Medicine. Volume II. Edited by Dr. Hobart Amory Hare. 8vo, 334 pages. Illustrated. Lea Brothers & Co., Philadelphia and New York.

Diseases of the Nose and Throat. By Dr. D. Braden Kyle. Third edition. 8vo, 669 pages. Illustrated. W. B. Saunders & Co., Philadelphia, New York and London.

Medical Diagnosis. By Dr. Wilhelm v. Leube. Translated and edited by Dr. J. L. Salinger. 8vo, 1,058 pages. Illustrated. D. Appleton & Co., New York and London.

Diseases of Metabolism and Nutrition. By Dr. Carl von Noorden and Carl Dapper. Translated by Dr. Boardman Reed. 8vo, 89 pages. E. B. Treat & Co., New York.

Obstetric and Gynologic Nursing. By Dr. Edward P. Davis. Second edition. 12mo, 402 pages. Illustrated. W. H. Saunders & Co., Philadelphia, New York and London.

ORIGINAL ARTICLES.

CONSERVATISM IN OTOLOGY.[1]

BY GORHAM BACON, M.D.,
OF NEW YORK;
PROFESSOR OF OTOLOGY, CORNELL UNIVERSITY MEDICAL COLLEGE.

DURING my term of service as house surgeon in Bellevue Hospital, many years ago, I was inclined to feel that, if the attending surgeon came to the hospital and decided not to operate at once on a case that seemed to me to demand immediate attention, such a man was either "growing old" or else had "lost his nerve." Although conservatism seems to belong more particularly to those who have had considerable experience, I am unwilling to plead that I am either old or that I have altogether "lost my nerve." In using the word conservatism, I do not wish to convey the impression that I am at present less inclined to operate than formerly, for such is not the case. "The time to operate" in otology is the most difficult problem for the aurist to solve, and I feel that in some cases there is too great a tendency to operate too early, rather than to try what conservatism can do.

During the past fifteen years, one would be surprised to read in medical literature of the number of operations that have attracted the attention of otologists throughout the world. It is only a few years ago that the medical journals were filled with reports of successful attempts to improve the hearing in cases of chronic catarrhal deafness, by excision of one or more ossicles. To-day this operation is seldom performed and is generally condemned, not only, as being of no benefit to the patients, but in many instances as having made the hearing worse.

Then again, electrolysis a few years ago was brought forward as a successful method of relieving this most unfortunate class of patients, but alas, with the same results. During the past few years the medical journals have been filled with reports of operations on the mastoid, the sigmoid sinus, the internal jugular vein and the brain.

Of late, the attention of otologists has been devoted to the so-called radical operation for the cure of chronic purulent otitis media, and it is to this class of cases that I wish more particularly to call your attention, for I feel that in many cases at least a cure can be brought about by more conservative methods of treatment. The radical, or so-called Schwartze-Stacke operation, consists in opening up the mastoid antrum by making an incision behind the ear as one would do in a mastoid case, and then by cutting away sufficient bone to transform the middle ear, attic and antrum into one large cavity. The wound being closed behind, cicatrization is often hastened in this new cavity by means of skin grafts. This operation is one of the most important in otology, for, when properly and successfully performed, the patient can certainly feel that any future danger from an intracranial complication is practically impossible. To recommend, however, that this operation should be performed in every case of chronic purulent otitis media, is, in my experience, absolutely wrong.

In a conversation held a short time ago with a physician living near New York, I was very much impressed with a statement which he made in talking about patients with ear troubles. He said that since the number of operations had increased so materially during the past few years he had considerable difficulty in persuading his patients to go to the city for advice, for they felt that in consulting an otologist in New York the term simply meant that they surely would have to undergo an operation. When an operation once becomes, as it were, "fashionable or popular," there is always a great danger that it will be performed unnecessarily in many instances, and I feel that this is true not only of the mastoid operation, but more particularly of this so-called radical operation.

An erroneous impression is frequently conveyed to the mind of the general practitioner when he reads the reports of so many successful operations, and from the teaching of many he feels that an immediate operation is imperative in every case of chronic discharge from the ear. To illustrate this point, I would refer to a patient who recently came in great haste to my office and was in a very nervous state because the physician, whom he had seen in his town, had told him that he ought to be operated on at once as his life was in great danger. On questioning him, I found that he had had a discharge from one ear for years, and that the doctor had not even made an examination, but on the theory that a chronic discharge from the ear occasionally extends to the brain, had scared him most successfully. To show what can be accomplished in some instances at least, by conservative methods, I would call your attention to the report of the following cases:

Case 1.—Mrs. O., about fifty years of age, came to see me on October 2, 1901, and gave the following history:

Three years ago she had an abscess in the left ear and since then has had a discharge at times, for which she has received treatment; granulations have been removed at intervals.

When I first saw her in October she was in a

[1] Read at a meeting of the Society of the Alumni of Bellevue Hospital February 3, 1904.

very nervous state of mind, and had lost considerably in weight and general health, on account of the advice she had received from a specialist who, after an examination, told her that she ought to have an operation at once as she was likely to die at any moment from a brain complication.

On inspection of the ear, I found a moderate-sized perforation in Shrapnel's membrane with a slight discharge and very little odor. There were no evidences of a cholesteatoma and I was satisfied from an examination with a probe that there was but a slight roughness of the bone, and that a conservative line of treatment could safely be carried out.

She had no cerebral symptoms. Hearing for watch: right ear, 17 inches; left ear 1½ inches. Bone conduction increased on the left side. The right drumhead showed the usual evidences of a chronic catarrhal inflammation.

The patient was given tonics, etc., and the local treatment consisted in establishing good drainage from the attic and washing out the cavity with a bichloride solution 1 in 3,000 through a middle-ear syringe, and afterward injecting a solution of boric acid in alcohol into the attic. The discharge became less at once and her general health was very much improved. She was seen occasionally during the winter, and as the disease was yielding satisfactorily to the treatment I persisted until April 10, when the discharge ceased and cicatricial tissue covered over the roughened bone. The ear has remained perfectly dry during the past two years and she has required no further treatment. Her general health has greatly improved.

Case II.—October 13, 1902, H., a lawyer, forty years of age, consulted me on account of a chronic purulent discharge from the right ear, which he has had from childhood. He states that he has had a polypus removed several times; that the ear has discharged at intervals, but has been otherwise quiescent. The hearing for the watch was, right ear, 3½ inches; left ear, 51 inches. Bone conduction increased on the right side. Raised voice heard with the right ear 10 feet. An examination showed that a large portion of the posterior half of the drumhead had been destroyed, that there was a large opening leading up to the attic behind the short process, and that there was no obstruction to good drainage.

The only symptom which gave him any concern was a slight dizziness of late. A probe could easily be passed into the attic which revealed a slight area of roughened bone with some hypertrophied mucous tissue.

Before coming to see me he had consulted a physician who told him that he ought to have an immediate operation, otherwise he might die very suddenly. He said that he would like to postpone an operation until later in the year as he had some important law cases which occupied his attention. I told him that in my opinion he could do so. The same line of treatment was carried out as in the preceding case, viz., cauterizing the hypertrophied tissue and establishing good drainage and the use of the middle-ear syringe. In a month's time there was marked improvement. Two months later the ear was dry and has remained so ever since. The slight vertigo disappeared and was probably due to pressure on the foot-plate of the stapes caused by granulation tissue.

To prove that I am not at all opposed to operative interference in suitable cases, I would ask your consideration of the following cases:

Case III.—H. L., forty-five years of age, came to see me on February 20, 1900. He gave a history of having had an earache and abscess in the left ear ten years ago; ever since then there has been some discharge and of late there has been some odor. An examination showed a perforation high up in Shrapnel's membrane with evidences of carious bone. I explained to the patient that I was willing to try a conservative line of treatment, but that there was no doubt an operation would be the best procedure in this instance.

He preferred to postpone any surgical interference. I washed out the cavity with the middle-ear syringe and afterward injected various astringents, carrying out this line of treatment till the middle of May. The discharge ceased and he had no further trouble until October, 1901, when he returned to my office. At that time I found granulation tissue protruding from the former opening and I advised operation. From this time on until December 5 I tried to reestablish drainage to no purpose. Sagging of the upper wall of the canal took place and masses of cholesteatomatous material were removed frequently from the attic by means of a blunt curette.

On December 5, under ether anesthesia, I performed the usual Schwartze-Stacke operation, by cutting down on the mastoid process close to the auricle. The line of incision extended from the tip to a point about an inch above the superior attachment of the auricle. I opened the antrum with chisels and found a large cavity filled with cholesteatomatous material, all of which I removed. I transformed the antrum, attic and middle ear into one cavity and thoroughly removed all carious bone and ossicles, and included in this cavity the upper cells of the mastoid, leaving in situ the lower portion of the bony external auditory canal. I then divided the cartilaginous canal longitudinally. The wound behind the auricle was completely closed by sutures. Narrow strips of gauze were then packed through the canal into the middle ear so as to force the divided cartilaginous canal walls against the walls of the new cavity. A layer of gauze and cotton was then applied and the ear bandaged. The stitches were removed in a few days and the cavity was washed out regularly with a bichloride solution through the external auditory canal. In six weeks' time the entire cavity was healed and cicatrization had occurred. The patient has had no further trouble with his ear.

Case IV.—Mrs. D., a graduate nurse, about forty-five years old, consulted me on April 5, 1902, and gave the following history: In 1882

she went sea-bathing, and got water in her left ear. She had a severe earache attended with great pain, and followed by a discharge. She admits that she has neglected treatment. She had no further trouble until 1893 or 1894, when she had a recurrence of the pain and discharge. She has had pain repeatedly since then and there has been at times more or less discharge. Last January she had severe pain for eight days. At that time she came under my care and I have been looking after her since. The soft tissues of the upper canal wall were then swollen and drooping and I succeeded in removing cholesteatomatous masses from the attic through a perforation in Shrapnell's membrane. Granulation tissue was also excised. The indications for an operation were clearly marked, as there was an obstruction to the flow of a fetid pus, the cholesteatomatous material could not readily escape and there was considerable danger that the disease might extend to the brain.

She could not, however, then consent to an operation as she felt that she could not spare the time.

On April 5, however, the symptoms had become more marked; she had a troublesome tinnitus with considerable vertigo. She was also extremely nervous.

On April 8, under ether anesthesia, I opened the mastoid antrum and performed the Schwartze-Stacke operation (a short description of which I have already given). I found considerable cholesteatomatous material and a carious condition of the attic and ossicles. These masses were removed, also the ossicles and drumhead and the attic and antrum scraped with a sharp spoon. The patient stood the operation well, but suffered on the second day from extreme nausea and vomiting, which continued for several days. In two weeks' time the wound behind the auricle had entirely healed and six weeks later the middle-ear cavity was healed. I saw her in the following October and she was greatly improved in general health. The noise in the ear had ceased. She has had no further trouble.

Case V.—A. F., thirty years of age, came to see me on October 21, 1901, on account of a chronic discharge from the right ear, following scarlet fever in childhood. The hearing for the watch was, right ear, 2½ inches; left ear, normal. Bone conduction increased on the right side.

An examination showed that there was a perforation in Shrapnel's membrane, which led to carious bone in the attic, and there was a very offensive discharge containing cholesteatomatous masses. I advised an operation, as it was impossible to establish good drainage and he was subject to frequent attacks of earache. November 23, under ether anesthesia, I made the usual incision behind the auricle and over the mastoid, and exposed the antrum. I removed the ossicles which were carious, as well as the remnant of the drumhead and cut away the upper part of the bony auditory canal. Granulation tissue and softened bone were removed from the antrum, attic and middle ear, and the wound closed in the usual way. The cartilaginous canal was divided in a longitudinal direction, and pushed against the newly made cavity. The wound healed nicely and in six weeks' time the ear was entirely dry and has given no further trouble.

After the discharge has been cured by the Schwartze-Stacke operation, the patient's general health is usually very much improved, which is generally shown by an increase in weight, so that when this operation is clearly indicated, not only is the general health greatly improved, but the danger of a intracranial operation is practically impossible.

There are, however, several points that I would like to call to your attention this evening. In the first place, in considering the advisability of an operation in a patient suffering from a chronic otorrhea of long standing, we should determine first of all, as to whether the perforation is sufficiently large for the purpose of drainage. If the opening is large and we can readily pass a probe into the attic and find but little carious bone, I feel that it is our duty first of all to try to cure the disease by means of injections through a middle-ear syringe. There is but little chance of the disease extending to the brain, if the patient is properly treated.

Solutions of bichloride 1 in 3,000, should be used, followed by injections of boric acid in alcohol or iodoform and alcohol. Peroxide of hydrogen should never be used in such a perforation. Exuberant granulations should be removed, and everything done to establish good drainage. If, however, a patient comes to us, who complains of frequent attacks of earache, and on examination we find that good drainage is impossible, owing to a small perforation, and that the ossicles are carious, that the discharge is fetid and contains cholesteatomatous masses, and, moreover, if we detect a carious condition of the attic, we should, under such conditions, advise an immediate operation unless we feel that conservative treatment can be first attempted.

Occasionally, such a patient is apt to have frequent attacks of mastoid inflammation, as shown by sensitiveness on pressure over the mastoid process. In such cases, an operation is clearly indicated, for such a symptom shows that the disease has extended to the mastoid cells, and is likely to extend into the middle cranial fossa very rapidly, as the outer cortex of the mastoid in such instances is usually very hard and thick.

Other symptoms calling for an early operation, are headache, nausea, vomiting and vertigo. The danger of an intracranial complication is very much greater in hospital patients, for they generally wait until some serious symptoms develop. So that an erroneous impression is frequently conveyed to the mind of the general practitioner by the report of serious, and, in some instances, fatal cases of chronic otorrhea.

There is one other point to which I wish to refer, in speaking of conservatism, and that is, that in all operations on the mastoid process, and

in operations for brain abscess and sinus thrombosis, there is at the present time a great tendency to make too extensive incisions over the mastoid and in the neck, without any regard to subsequent disfigurement of the patient. If we remove too much bone from the mastoid we are liable to have considerable depression, and the auricle does not return to its natural position afterward, especially if we carry our incision too far upward, and curve it over the auricle in the temporal region.

In concluding, I would like to say that in every instance we should try to cure our patients without an operation, if possible, and we should remember that every operation is attended with a certain amount of danger.

In the Schwartze-Stacke operation there is always a chance of injuring the facial nerve, and while the paralysis is frequently only temporary, there is a possibility of its being permanent in certain cases.

INTRAHEPATIC CHOLELITHIASIS.

BY EDWIN BEER, M.D.,
OF NEW YORK.

(Continued from Page 209.)

Without going any further into details, it might be well to sum up the results of this investigation as far as I have gone. The observations are of decided theoretical importance. Here we have experiments similar to those of Mignot, Miyake, Italia,[40] and others, not in animals, but in man. In a process as intricate as that which leads to gall-stone formation, many are loath to accept all that animal experimentors observe, and with perfect justice, as there are decided differences between man and lower animals, differences which are not only chemical, but also anatomical.[41] Moreover, the results in animal experiments have not been regularly successful, and, even recently, Wolynzew[42] has reported complete failure.

In animals the cystic duct was obstructed, and bacteria introduced. In our cases the common duct was obstructed, and bacteria, that infest the lower one-third of the choledochus, spread into the system of ducts. In both cases stagnation is followed by inflammation—in both cases gall-stones are produced. In animal experiments, in the gall-bladder, in human beings, in the liver ducts. Thus we have the direct proof that gall-stones in man result from infection of the biliary system—that the gall-stones are the result of a local inflammation. Moreover, these cases show that there is something else that influences the production of stones, as all cases of stagnation and infection do not lead to stone formation. Whether this third factor is a diathesis, as the French authors say, or a disposition, as Riedel puts it, must be decided by the collection of a very large number of cholangitic cases, and, by experimental work.

That there can be no difficulty in applying these same facts to gall-stone production in the gall-bladder is self-evident. What applies to the intrahepatic ducts, applies equally to the gall-bladder. The reason that stones form in the bladder so much more frequently than in the liver ducts is undoubtedly to be found in the fact that the local stagnation in the gall-bladder is a frequent occurrence, whereas stagnation in the liver is rare. Infection in the stagnant gall-bladder is also much more frequent than an intrahepatic cholangitis. These factors undoubtedly explain the greater frequency of gall-bladder stones. But in the gall-bladder, as the result of every cholecystitis, stones do not form; a similar third factor seems to play a part here, just as in the cholangitis cases.

Another point of theoretical interest is the fact that gall-stones do not develop in stagnant bile in the ducts, except when the inflammatory process is purely catarrhal, and fail to develop when the process is suppurative.

Recently Ehret and Stolz[43] found, in a case of cholangitis suppurativa no stone production, and in a case of purulent cholecystitis no cholesterin in the gall-bladder contents. To harmonize these findings with the experimental work in animals, the conclusion that mild inflammatory processes alone lead to stone formation seemed warranted. In my own, and in Kehr's cases, there is no doubt that stones developed in the intrahepatic ducts as the result of a suppurative cholangitis. As yet, however, there is no proof that a suppurative cholecystitis will lead to stone formation in the human gall-bladder. Such cases are operated, or are fatal before the necessary time elapses for stone formation, or they recover and no one knows what has taken place in the gall-bladder.

Both series of cases, Kehr's and mine, also demonstrate clearly that stones of good size can develop within three months, which is much faster than was thought, and more rapidly than Mignot (five to six months), Miyake (six to twelve months), and Italia (four months), succeeded in producing calculi experimentally.

From the foregoing it is evident that gall-stones are found within the liver ducts more frequently, and more regularly, than is generally admitted. They are perhaps always present, if a cholangitis develops secondary to obstruction of the choledochus by stones, provided the condition lasts longer than one month, gravel, in all probability, being present at an earlier stage.

In considering the structure of these intrahepatic stones, one is impressed, as said before, with the purely local shapes of many of the specimens. Though distinct tetrahedral stones are found mixed in with a lot of bile gravel, still many stones have shapes suggestive of their duct origin. These peculiarities have been touched upon before, in discussing the views of Charcot and Langenbuch.

In one of my cases (VI), in which the stones were as large as cherry pits, the stone nearest the porta hepatis was fairly well rounded, fitting tightly in the duct, while the stone situated next to it, and more centrally in the liver with regard to the choledochus, was distinctly, though irregularly, faceted, and of the same size. They both were brown in color, and contained pigment and

cholesterin. In another case I found one almost pure bilirubin calcium tetrahedral stone, hidden away in the ducts of the right lobe. In another instance the calculus was a long ovoid, containing pigment and cholesterin. Its color was black, and it looked like a miniature sausage, almost one cm. long. Peters[44] has reported distinctly branched calculi. At times, one finds the calculi still soft in the intrahepatic ducts, fitting these like molds, and composed of pigments and cholesterin. At other times the calculi seem conglomerates of bile gravel.

From the literature, the impression is obtained that intrahepatic stones are regularly composed of pigment, bilirubin, or its derivatives combined with calcium, but, from the above, it is evident that cholesterin here, as in the gall-bladder, is a very frequent factor. In the gall-bladder, pure cholesterin stones seem to form despite the fact that bile is present, as the cysticus is patent when the stone is discovered. It is difficult to understand how such pure stones can develop in the gall-bladder if bile is present, and just the same difficulty applies to the cases of pure cholesterin stones in the liver, such as Czerny[45] and Cassaet mention. The possibility of a secondary substitution of the bile pigment in the primary stones by the infiltration of cholesterin, may have a part to play in the production of these pure cholesterin calculi.

In the literature other peculiarities of these calculi in the ducts are mentioned as rarities. Laboulbène[46] and Peters have seen distinctly branched calculi corresponding with the pictures of casts of bile ducts from the interior of gall-bladder stones, portrayed in Thudichum's book. Naturally the latter are minute, microscopic even, whereas the former are not. Glisson had described a similar kind of stone in cattle, and it is spoken of as resembling coral. Calculi of tubular shape have been found, but these also are rarities.

The usual types are the pigment, and pigment and cholesterin calculi. They are small in the early stages, but if they remain in the liver they may grow to the size of cherry pits or hazelnuts. With these calculi are found deposits of pigment sand in the early stages, but later, when the bile streams on into the bowel, the sand may pass out and the stone remain imbedded in the liver duct. Facets are not regularly found, but as in several of my cases and in a number in the literature such facets are distinctly present. The method of their production is very obscure. Until a large number of such stones are gathered, and examined with great care, it will remain undecided. Probably factors similar to those in the gall-bladder are at work here. The general shape has been sufficiently discussed, as well as the frequent intimate relation between stones and ducts, but it must be mentioned that occasionally the ducts in the liver become irregularly dilated, little sacs form and the stones grow in these.

So much for the intrahepatic stones, their causation and frequency of occurrence. Another side of this subject presents itself, and now we must see whether these little stones are of any practical importance. This has been denied on the one hand, and on the other it has been asserted by various clinicians, but the first operator to come in contact with them, provided the above analysis of his cases is correct, happened to be Kehr, and their presence in part affected his surgical procedure.

Such intrahepatic stones may remain in the liver, and this applies to those that develop there as well as those that wander into the liver from the bladder, and may cause absolutely no bad effects. They may, however, lead to a variety of results in the liver. On the other hand, they may wander, and perhaps here is the chief source of danger. Still it must be admitted that, though they may lead to unfortunate results as far as we know, in the past they do not seem to have done as much harm as one would expect, seeing how regularly they follow cholangitis and choledochus obstruction due to stone. Whether this phase of the question has escaped attention just because extrahepatic stones have not been regularly examined to determine their possible intrahepatic origin, and because the intrahepatic ducts have not been carefully followed and the condition of intrahepatic stones has been ignored, is difficult to say, though such an explanation is very likely correct. A great many difficulties are encountered in this realm and in years to come when we are more perfectly equipped we shall recognize the results that follow intrahepatic cholelithiasis more easily and more frequently. Still at the present day it is possible, by using the extensive literature, to arrive at some conclusions as to the possible results of such stone formation.

If we concern ourselves with the stones that move out of the liver ducts and become extrahepatic, the most likely result is that they will pass off into the intestine. Whether that is really true can not be determined at the present time. On the other hand, it is pretty generally conceded that these intrahepatic stones may wander into the gall-bladder and there act as the nucleus for larger stones. It can not be denied that many gall-bladder stones have a pigment nucleus, but to ascribe this to intrahepatic origin in every case would be unjustifiable. Thudichum has upheld the intrahepatic origin of these nuclei more energetically than anybody else. Lawson Tait[47] and Hein expressed similar views. The casts of ducts that Thudichum found inside of fresh gall-stones have not been found by subsequent investigators. Naunyn says he did not see them. I have been able to convince myself that one can wash out of the center of fresh calculi pigment masses of different shapes, some of which under the microscope are distinctly branched. They are not regularly found nor do they suggest casts of biliferous ducts, but rather a chance apposition of small pigment masses. Although this view of Thudichum has not gained great favor, as is natural seeing that the proofs are lacking, many authors are willing to admit that the intrahepatic bilirubin

calcium stones may form the nucleus of stones in the gall-bladder. Naunyn admits this without in any way invalidating his position with regard to Thudichum's theory. On page 49 he says: "The intrahepatic bilirubin calcium stones constitute a peculiar and separate group. They seem, not infrequently, to act as foreign bodies in the gall-bladder, and produce here the symptoms of cholelithiasis. It is, at least, very striking how frequently these small stones which form in the liver ducts are found as the nucleus of cholesterin stones in the gall-bladder. I possess several collections of 20 to 30 calculi from different gall-bladders, each calculus containing as nucleus such a bilirubin calcium stone."

More recently, 1899, Hoppe-Seyler has expressed a similar view. No doubt the nucleus of many gall-bladder stones contains material identical with that of intrahepatic pigment stones, but why should not the same chemical combinations be effected in the gall-bladder as result in the intrahepatic ducts? Bilirubin calcium stones occur in the gall-bladder as well as in the liver ducts, though seemingly even less frequently. The size of the nucleus and the material, as well as the frequency with which gall-bladder stones bearing such a nucleus occur point perhaps to a source for the pigment nucleus other than the gall-bladder. How regularly such an extra-bladder origin is present can not be stated.

Laboulbène's[48] and perhaps Cassaet's[49] cases show that this intrahepatic origin of gall-bladder stones is not pure hypothesis. Laboulbène found coral-shaped calculi in the bladder and similar smaller calculi in the "canaux hepatiques," which, according to Charcot, Bouchard and Brissaud,[50] is an instance of intrahepatic stones that have wandered into the gall-bladder and grown there. Chemically and physically the stones were similar. In both positions they were coral shaped and contained products of the oxidation of bilirubin and very little cholesterin. Cassaet's case is similar but less conclusive, as his calculi lacked the morphological identity of structure. Still he concludes: "*Pour parler plus exactement les gros calculs n'étaient formés que par la conglomération des petits.*"

It is evident from all this that one of the distinct dangers of an intrahepatic stone formation lies in this wandering into the gall-bladder and there growing into an adult stone. Another danger rests in these stones remaining in the common duct and growing there.

It has been the custom to underestimate the importance of smaller calculi, as they, being small, would naturally pass into the bowel. Since it has become appreciated, however, that the symtoms of gall-stones owe their origin to inflammation, that biliary colic does not mean a rough stone working its way into the intestine but inflammation and impaction, the smaller stones have been found at the bottom of much trouble. Deaver[51] has put this very distinctly, saying "the presence of a calculus, even if insufficient in size to produce jaundice, will impair the drainage of the duct and induce a train of symptoms causing chronic invalidism."

In Riedel's[52] recent book a similar appreciation of small stones is found on page 102, where, in speaking of the treatment of stones in the choledochus, he says: "Nothing is more liable to lead to unfortunate consequences than the breaking or crushing of a stone in the choledochus, as all the fragments can not be removed. If one fragment remains in the duct, the result of the operation is nil."

In another passage he tells of cases that had to be operated a second time when after a new attack minute stones that in the first operation could not be felt in the choledochus were removed.

These are not isolated views, but many of the most experienced gall-stone surgeons have come to these same conclusions. Thus it is evident even the small intrahepatic stones may lead to trouble here in the choledochus. How often they will do so is another question. That it is a danger can not be denied. Perhaps the serious results in such cases as Kehr reports are really due to intrahepatic cholelithiasis and impaction of an intrahepatic calculus at the papilla and not due to a stone being left by oversight in the choledochus at or after the operation.

Kehr's assistant, Berger, has undoubtedly gone too far, in saying that every stone and every fragment that is removed by hepatic drainage means the prevention of a certain relapse.

If that were so, seeing how frequently intrahepatic stones form in the cholangitic and obstructed ducts, we would have heard, it seems to me, of more recurrences after choledochotomy without hepatic drainage, for even Kehr, before he used this form of drainage, did not have anything like the percentage of recurrences that Berger's statement would indicate. Berger's enthusiastic conclusions can not be shared.

From the above analysis, however, I think that one is justified in saying that intrahepatic stones may wander into the common duct and cause trouble there just as well as they can get into the gall-bladder and become the nuclei of larger stones. These two consequences are, no doubt, the most important and most frequent unfortunate outcomes of intrahepatic stones, provided they move out of the liver and do not get into the duodenum. If they remain in the liver, they may cause no trouble at all, as in my case of stones in the left lobe of the liver, without any bad effects either in the organ or clinically. On the other hand, there is no doubt that such calculi may be a source of danger, even if they remain in the liver.

These dangers are chiefly in the nature of inflammatory changes, whether they establish a locus minoris resistentiæ, or whether by developing in the smaller infected ducts they cause retention in the more central part of the duct, while the rest of the system is freed by removal of the obstruction of the choledochus, is unknown.

Langenbuch,[53] in speaking of stones in the

ducts, writes: "Such wanderers remain in their new site and lead to decubitus and abscesses or the flow of the bile drives them back into the common duct." Such ulceration about a calculus might lead to structure of the duct and formation of fresh stones deeper in the liver. Stones that remain in the liver may lead, at the place they are impacted, to a marked inflammatory reaction in the adjacent tissues, so that "cysts with thick, firm walls develop, enclosing the calculus, while the parenchyma in the vicinity remains normal or becomes indurated, or undergoes degenerative changes." Frerichs has also called attention to the possibilities of such stones causing pylephlebitis and abscess. Geigel[54] emphasized the relation of the vessels about the ducts to the portal system and the possibility of liver abscesses from this source. Budd had previously called attention to this. In such a way intrahepatic stones may lead to abscesses in the liver as well as by the purely local pericholangitis about the intrahepatic stones.

How often intrahepatic stones lead to abscess is as yet unknown. There is no doubt that gall-stones are found in hepatic abscesses, but in these cases the examination of the intrahepatic ducts has been disregarded, so that it is impossible to decide whether stones resulted from the abscess or led to the same, though the latter view is the more likely.

If intrahepatic stones get lodged in the larger ducts in the left or right hepaticus they might lead to the results Nasse[55] obtained after ligation of one of these. Courvoisier reports an atrophy of the liver in some of these cases. Perhaps it is the analogue of the experimental atrophy produced by Nasse.

Whether stones in the hepaticus proper are of gall-bladder or hepatic origin is still disputed. Most authors favor the former view, whereas Naunyn, though he says that the gall-bladder is the usual origin of hepatic stones, still admits an intrahepatic origin of some of them.

From all the above it is clear that intrahepatic stone formation, as well as the wandering of gall-bladder stones into the liver ducts, may lead to a variety of unfortunate consequences which may be of the greatest moment to the patient. Perhaps the most likely result is a recurrence of the patient's gall-stone symptoms, due to wandering of intrahepatic stones into the gall-bladder or into the common duct. Time will show how important this is as a factor in the so-called "Recidivs," which have been so frequently magnified by the internists and so persistently minimized by the surgeons.

If Naunyn's theory of the purely local inflammatory cause of gall-stones were true, one would expect that the inflammation that leads to the first gall-bladder stones would repeat itself and result in fresh stone formation. If such a fresh stone formation occurs the future of operated patients, provided of course the gall-bladder is not removed, is not certain. Such a new formation (a true recurrence) must be distinguished from a false recurrence or a recurrence of symptoms due to unremoved stones or to secondary and postoperative adhesions, herniæ, etc. This distinction is, of course, very difficult clinically, but it must be insisted upon if the question of real recurrences is to be definitely settled. Internists have been citing cases as real recurrences where, as Kehr has repeatedly pointed out, no certainty could exist as to the complete removal of all the stones. In answering the question one must use the cases in which a radical operation has been done. As Kehr says, in all cases operated in the acute stage, as well as in all cases not operated by ectomy and hepatic drainage, stones may be left in so that these cases can not be used in discussing actual new formation of stones.

Czerny, Körte, Poppert, Riedel and Kehr (1900) have reported no real recurrences, and, as said before, they are inclined to think such a new formation is very exceptional. Naunyn,[57] on the other hand, says, "Even if all stones are removed, that does not prevent a new formation of stones." It is evident from the cases of intrahepatic stones that Naunyn's view is correct, that the stones in the liver are produced at a time when the other stones are in the gall-bladder and more or less independent of the bulk of these. The intrahepatic stones that develop there are theoretically, and at times clinically, real recurrences.

In addition to this evidence of a fresh production of calculi other evidence is found in the stones in the gall-bladder. Leichtenstern said that "in the great majority of cases the formation of stones is effected at one time, and that process is not repeated during the rest of the patient's lifetime." Or, as Naunyn says, "The calculi in a gall-bladder are usually, as Hein and Bramson pointed out, both of the same age and of the same composition."

No doubt these statements are in part true, but it is just in the exceptions that we see the production of stones at different times. In one gall-bladder, for instance, I found a large number of stones which varied in size from a walnut to a pea, but the intervening or intermediate sizes were remarkably definite, so that I could, without the slightest difficulty, divide the stones into five groups, according to their sizes. The composition and layers of the stones did not correspond, and the largest stone was pure cholesterin and the others were mixed. Not only was this ready division and separation possible, but the number of representatives of each generation of stones varied, so that the largest and oldest stone was single, the next generation and next in size represented by eight, and so on to the pea-sized stones, that were most numerous, numbering over 100 in all.

No doubt everybody has seen similar stones repeatedly, but Riedel,[58] with his large number of cases to draw from, shows that this arrangement is very frequent. He says: "Multiple generations were observed in ten instances (31 per cent.)." Thus in 326 cases that could be used for this estimation, he found multiple generations in one-

third of the cases, just as frequently as he found one to three stones in the bladder. This is excellent proof that the possibility of gall-stone production at different times exists.

The cases of gall-bladders in which silk sutures have been left at operation, and stones formed about them, are equally good proof that stones may form again. These facts and the relation of intrahepatic cholelithiasis to extrahepatic must be considered in the discussion of real recurrences. The possibility of such new formation can not be denied. How often after cholecystostomy it occurs, in the gall-bladder, is a problem of the future, just as the determination of the frequency of the advent and growth of intrahepatic calculi in the gall-bladder.

The most radical method of dealing with gall-stones, and the one which aims at getting rid of all these dangers, is that advocated by Kehr. If the gall-bladder is removed, no stones can form there again. If to ectomy is added choledochotomy and drainage, stones in the ducts which have or have not caused symptoms will be removed by the operation or by the subsequent drainage of the choledochus and hepaticus. This combination of operative procedures has proven very successful, as far as immediate results are concerned. In 17 per cent. of his 93 cases during the after-treatment stones and fragments have been removed by lavage and drainage of the ducts. A suture of the choledochus at the operation would have run the risk of recurrence in many of these cases.

As yet no method seems to approach this in its ability to deal with the secondary intrahepatic formations, as well as the stones that may have wandered into the intrahepatic ducts from the gall-bladder, and even though it may fail to remove all of these, as was shown by autopsy in one of Kehr's patient's, who died some eight days after the operation, still it surely does much more for the prevention of "Recidivs" from this source than any other method. In cases of cholangitis the drainage of the hepaticus must be carried out if these new fragments and stones are to be removed.

A large number of cases of stone in the common duct that have had signs of obstruction have also had cholangitis, and although at the time of operation no sign of cholangitis is present, the intrahepatic stones must be considered and dealt with. From an examination of the bile obtained at operation, unless done under the microscope and by biological methods, one can not be sure that a cholangitis is not present.[59] Moreover, as Riedel[60] has recently shown, a most extensive suppurative cholangitis may be present and give no symptoms. He saw three such cases, and one of my own resembles Riedel's series.

Opinions of surgeons are still at variance as to the advisability of drainage of the hepaticus. Some oppose it except in the severest cholangitic cases, while Kehr considers it the ideal operation in non-acute cases, even if cholangitis is not present. From the cases brought together in this paper, from the study of the causation of intrahepatic stones and their possible relation to recurrences, as well as to future changes in the liver, it would seem that drainage of the hepaticus was the only method of operation for even mild cholangitic cases as well as for cases that have had symptoms of choledochus obstruction and cholangitis at some previous time, though the immediate cause of the present operation may be in the gall-bladder itself.

Another practical conclusion can be drawn from this study. Courvoisier said that a choledochus obstruction should be relieved at an early date to avoid the formation of intrahepatic stones. Here we are between two fires. As is well known, early choledochotomies are liable to lead the operator into trouble. The duct may be empty, the stones having passed, or the duct may be filled with countless stones. When a stone and cholangitis are certain an operation before the second month naturally would avoid the danger of intrahepatic stones forming and future trouble. This problem, purely therapeutic in character, scarcely enters the scope of this study, though the decision as to when to operate is of great interest and importance. It must, however, be emphasized that the earlier the operation the less danger there is of intrahepatic cholelithiasis.

In closing, I wish to express my gratitude and thanks to both Professor Ghon and Docent Stoerk for their many kindnesses.

OBSERVATIONS ON DILATATION OF THE STOMACH AND ON GASTROPTOSIS.[1][2]

BY ROBERT COLEMAN KEMP, M.D.,
OF NEW YORK;
CONSULTING PHYSICIAN, GASTRO-INTESTINAL DISEASES, MANHATTAN STATE HOSPITAL, WEST, WARD'S ISLAND; PROFESSOR OF GASTRO-INTESTINAL DISEASES, NEW YORK SCHOOL OF CLINICAL MEDICINE, ETC.

The subject of this paper, "Dilatation of the Stomach, Gastroptosis and a Discussion of the Methods of Physical Diagnosis in Diseases of the Stomach," would seem to me to be of interest not only to the specialist and the surgeon, but also to the general practitioner of medicine, upon whom the first diagnosis of the case depends and upon whose judgment so much responsibility is placed.

My paper is the result of a series of observations made during the course of my service in grastro-intestinal diseases at the Manhattan State Hospital, West, Ward's Island. It also includes cases from the Manhattan State Hospital, East, which institution I am visiting for Dr. Thomson.

These two hospitals have as inmates over four thousand patients, male and female, equally divided, and furnish a fruitful field for investigation into the gastro-intestinal tract. I have also secured valuable material from my service in diseases of the stomach, at St. Bartholomew's Clinic and in my private practice.

I feel that I owe much to the courtesy of Drs. Dent and Macdonald of the Manhattan State Hospital and to the assistance of Drs. Delacroix, Meager, Holmes and R. Haviland of the staff. My associates, Drs. John E. Traub and C. T. Graham-Rogers have visited these institutions with me and assisted in my researches, and I have also received many valuable suggestions from my friend, Dr. Achilles Rose.

About a year ago, Dr. William H. Thomson first instituted a thorough research into the etiology of epilepsy at the Manhattan State Hospital, West, Ward's Island, and later extended his researches to the East Hospital. I was requested to take charge of that part relating to the gastro-intestinal tract. We expect, however, to continue this work for a considerable period of time, but as I have secured some rather interesting data from these institutions, as well as from other investigations, I felt that I should report them.

I would first call attention to the unfortunate fact that it has too often been the habit to depend on the examination of the stomach contents alone and to neglect the investigation of the motor functions and position of the stomach itself. As we shall demonstrate later, a prolapse of the stomach may exist without discoverable nephroptosis, and often with no enteroptosis that is detectable by the ordinary means of physical diagnosis. However, when a ptosis of the stomach exists, the intestines must necessarily accompany it.

We may find a hyperacid condition of the stomach, with the organ in its normal position; the same may occur with dilatation of the stomach and again hyperchlorhydria (hyperacidity) is a frequent concomitant of gastroptosis.

On the other hand, hypochlorhydria (or diminished acidity) may occur in a stomach occupying the normal position, also an organ that is dilated and in gastroptosis. Dr. Rose, for example, has demonstrated that certain symptoms attributed to gastritis may be due to gastroptosis. Cases of achylia gastrica have been reported, in which the stomach is diminished in size—including its containing capacity, the organ occupying the normal position. We have Dr. Einhorn's classical case, with practically no symptoms except rumination and a coated tongue. We have, furthermore, achylia gastrica in cases of marked dilation of the stomach and the same condition existing with gastroptosis.

These facts demonstrate that mere chemical analysis of the stomach contents is insufficient; but that we must in addition carefully investigate the motor functions and the position of the organ, in order to arrive at an accurate diagnosis and give a correct prognosis and proper treatment.

ATONY OF THE STOMACH.

It would seem to me of importance to discuss for a few moments "atonia gastrica" or "atony of the stomach," since this condition must necessarily first occur before dilatation of the stomach is produced. Even when a spasm, or stenosis of the pylorus is the cause of the dilatation, a mechanical atonic condition of the muscles of the stomach from exhaustion due to the resistant action of the pyloris, must occur before dilatation takes place. Atonia gastrica may be defined as a loss of tone or contractile power of the muscles of the stomach, so that the organ is distended and does not contract about its contents, with a resulting motor insufficiency.

Dr. Rose states that "atonia gastrica, dilatation of the stomach and gastroptosis are identical." I think that by this he means that dilatation of the stomach and gastroptosis are progressive degrees of atonia gastrica, and in this sense I agree with him.

In gastroptosis, I am aware that some dispute the dilatation of the organ; but my own observations cause me to state that such dilatation exists, as does necessarily varying degrees of motor insufficiency. It is inconceivable that in a condition of splanchnoptosis—a general relaxation and atony—with a descent of the viscera, that the

1 Read before the Medical Association of Greater City of New York, March 14, 1904.

2 Received for publication April 26, 1904.

stomach, as a matter of selection, should be exempt.

On the other hand, nature is a most beneficent mistress and affords us, literally speaking, many compensations—the most common example—compensatory hypertrophy in cardiac dilatation. Furthermore, in gastric conditions, we may have normal digestive functions, when examination has demonstrated that gastroptosis exists. There may be achylia gastrica without subjective symptoms. Finally cases which on examination show dilatation of the stomach, apparently suffer from no motor insufficiency, since within a brief period after administration of the test meal, practically no remains can be aspirated from the stomach. Whether this condition is due to a relaxed condition of the pylorus, or to a compensatory hypertrophy of the dilated stomach, is still a disputed question. Atonia gastrica, according to Dr. Einhorn, may occur as a complication of chronic gastritis, hyperchlorhydria (hyperacidity), neurasthenia gastrica, tuberculosis, heart disease, or any weakening affection and as a primary neurosis. My own observations lead me to state that the unfortunate habit of "bolting the food" may be an etiological factor.

As symptoms, there may be headache, diminished appetite, eructations of gas, a feeling of fulness after meals and constipation. Splashing sound is present and chyme is found six or seven hours after Leube's test dinner; others find it present also, two or three hours after Ewald's test breakfast. If, however, an hour after the latter, and we find 100 c.c. or more of contents associated with the above symptoms, we may consider the condition as atonia.

The stomach is found empty in the morning—in the fasting condition. Boas describes the descent of the greater curvature on the addition of water as a reliable symptom, but other disagree with him. Butler believes that atony of the stomach gives as symptoms motor insufficiency and moderate dilatation. It would seem, however, that the *condition has not yet progressed to dilatation.*

As to the splashing sound as a constant symptom of atony and as an aid to diagnosis, Drs. Einhorn and Rose have demonstrated that this is not always present, and also that it exists in many persons not troubled with digestive disturbances. Dr. Einhorn states that they have examined a hundred cases in regard to this special point. When present, however, it is an aid in locating the position of the stomach. Furthermore, to quote Dr. Einhorn, "In normal conditions a splashing sound can sometimes be produced by striking the abdomine with the hand." On examining the patient in the fasting condition, the existence of the splashing sound is of value in showing that the stomach is not empty and hence abnormal. This, however, is not a reliable sign and I perfectly agree with Debove and Redmond that sometimes, although rarely, the stomach may be found empty notwithstanding a splashing sound. Moreover, the absence of this phenomenon in the fasting condition does not by any means warrant the conclusion the the organ is empty, etc.

During my service at Ward's Island I have found the splashing sound to be absent in at least 40 per cent. of my cases of dilatation of the stomach and gastroptosis. They were proved to be such by both symptoms and transillumination of the organ. Splashing sound is of service when demonstrable, but unfortunately is quite frequently absent.

The treatment of atony of the stomach comprises hygiene, regulation of the diet, massage, hydrotherapy, electricity and the administration of strychnine.

DILATATION OF THE STOMACH.

Having described atony of the stomach at considerable length, believing it to be the preliminary stage, so to speak, of dilatation, we will now speak of dilatation of the stomach.

In effect, when do we consider a stomach to be dilated? Is it to be measured by its capacity alone, or by its capacity plus the alteration of its functions?

The capacity of the stomach is an extremely variable quantity. Ziemssen has shown that a stomach may be normal and only contain eight ounces, whereas another stomach, also normal, may possess a capacity of a couple of quarts. Boas has demonstrated that an apparently dilated stomach may really be in a condition of compensatory hypertrophy. We may, therefore, state the rule, *As long as the functions of the organ are normal, we cannot regard the conditions met with as pathological.*

In reference to the stomach itself, what is the chief point of differential diagnosis between dilatation of the organ and gastroptosis? Is it the degree of the descent of the lower border of the stomach? By no means. We see cases in whom the lower margin of the dilated stomach may have descended further than a stomach which is in the condition of ptosis.

In *dilatation of the stomach the lesser curvature maintains its relation to the diaphragm.* The muscular fibers first elongate in the vertical direction and the distance between the lesser and the greater curvature is increased. Dilatation may also ensue in the transverse and anteroposterior dimensions and the pylorus may be a little further to the right and in a slightly lower plane—but in general, the *lesser curvature maintains its relation to the diaphragm,* and this is the differential point between dilatation and gastroptosis. This feature is best demonstrated by transillumination of the stomach. Some authorities also claim that during transillumination the light follows the respiratory movements with dilatation, but does not do so with gastroptosis, and consider this a second differential point. My own observations do not confirm this view.

On the other hand, with gastroptosis the suspensory ligaments of the stomach are relaxed and the entire organ sinks; the lesser curvature as well as the greater, and in aggravated cases the lesser

curvature looks inward, to the right; the greater curvature, outward, to the left, and the pylorus may often lie below the level of the umbilicus. I have already given my views regarding atony and dilatation in cases of gastroptosis. The ptosis of the intestine, which is attached to the pylorus, readily explains the semi-rotation of the stomach on purely mechanical grounds. Curiously enough the vertical stomach is a return to the fetal position of the organ.

I might state that, though Dr. Einhorn employs the term ischochymia (retention of chyme) in place of dilatation of the stomach, I prefer the latter nomenclature, as more generally accepted. In addition, the retention of chyme is the result of the condition—the atony and dilatation.

I would furthermore call your attention to the claim of certain of our specialists that no dilatation occurs unless there is obstruction at the pylorus, either spasmodic or mechanical. In reply, I would state that we are all familiar with cases of chronic gastritis with dilatation of the stomach—in which there is no pyloric obstruction. I can show you numerous such cases at any of my clinics at Ward's Island. Furthermore, these gentlemen seem to forget the anatomical arrangement of the muscular fibers of the stomach, with the increased thickness and strength at the pylorus. In the atonic condition it is to be expected that yielding should occur at the points of least resistance, according to the ordinary laws of mechanics. The explanation is extremely simple and the theory held by these gentlemen would seem to me to be untenable, both on mechanical and clinical grounds.

In the discussion of dilatation of the stomach, I wish to first briefly refer to acute dilatation, upon which we may state there is comparatively little literature.

(1) There is acute dilatation as described by Einhorn, found as a result of acute inflammation of the mucous membrane of the stomach, due to errors of diet. It seems uncertain whether the dilatation is a result of pyloric spasm, or paralysis of the gastric muscles—possibly of both.

(2) Riegel describes a post-operative dilatation, especially following abdominal section. Some of the symptoms are apparently those of obstruction and yet secondary operation has demonstrated that such does not exist. The stomach is enormously distended with gas and there is vomiting. Lavage is of special value, as are also enemata, or irrigation of the bowel. This class of cases would seem to me to be the manifestation of an atonic condition, a paresis, so to speak, of the entire gastro-intestinal tract, the stomach as well as the intestines being distended. Dilatation of the stomach I believe to be an important factor and the general condition seems to correspond to our former nomenclature of postoperative intestinal paresis, which might be more correctly called gastro-intestinal paresis.[1] It would seem to be due to some shock of the sympathetic system, from the operation; at times to the anesthetic and later to uremia, or to sepsis.

(3) A third type of acute dilatation of the stomach which I have personally observed on several occasions, is in typhoid fever. In these cases there is not only acute distention of the stomach, but of the intestines as well. I can recall one case in which enormous distention of the stomach occurred, great quantities of gas being belched from that organ. The intestines also became suddenly distended, there were rapid respiration and a rapid and feeble heart with some shock. The differential diagnosis lay between acute gastro-intestinal distention and perforation of a typhoid ulcer. In many cases, I believe it nearly impossible to differentiate this condition from perforation, until the existing distention is relieved. In fact, I am cognizant of a case operated on at one of our large hospitals, there being the condition of dilatation as described above. No perforation was found and the patient died of postoperative shock. One important point in the diagnosis is, that perforation is first followed by local rigidity of the abdominal wall, which later becomes general. Hot stupes, hot drinks and enteroclysis are of value in relieving the distention. At times lavage, or the introduction of the stomach tube to relieve excessive gastric distention may be found necessary.

(4) A type of acute dilatation of the stomach is described by Mangelsdorf of Bad Kissingen. He examined over four hundred persons suffering from migraine, and found acute gastric dilatation during the attack. He also discovered this same condition just preceding many attacks of epilepsy. An excellent abstract of his article will be found in a recent number of *The Post-Graduate*, translated by Dr. Achilles Rose.

(5) Acute dilatation of the stomach may occur during the course of pneumonia, or other pulmonary diseases, and in such cases on account of of interference with the respiratory and cardiac functions may become a source of real danger. Indeed, the dangers of tympanites in pneumonia have been discribed by Broadbent and others. The stomach undoubtedly takes an active part in this distention and L. Emmett Holt, for example, calls our attention in his recent work on "Diseases of Children," to the dangers of dilatation of the stomach in pulmonary diseases. Regulation of the bowels, diet and gr. V doses of resorcin in adults are of value to prevent gas accumulation.

(6) In infants and young children, convulsions from overloading the stomach are not uncommon and emesis often produces immediate relief. I have noted acute distention of the stomach in these cases. Such attacks, continuously repeated, I believe may predispose to the convulsive habit and be a factor, in some cases, in the production of epilepsy.

(7) Acute dilatation of the stomach from indiscretions in diet may result in a cardiac attack, in effect be the cause of a pseudo-angina. I have at present a patient whom I have attended for

[1] This type of acute postoperation of the stomach, on pages 453 and 454 of International Medical Annual, 1904. An abstract from Walzberg from the *Arch. f. klin. Chir.*, Bd. 66.

over ten years and whom I have had under careful observation during at least twenty attacks. In these, the stomach is enormously distended with gas, there is belching of wind, escape of gas from the rectum, the heart action is rapid and feeble, the respiration rapid and labored. Emesis at once affords relief.

On a number of occasions the patient became entirely unconscious and extremely cyanotic. Only six weeks ago she had such an attack. While still unconscious she vomited a large amount of undigested food and there was an enormous escape of gas by mouth and rectum. There was immediate relief from all the symptoms. Cheese soufflée, mushrooms, and rich desserts, all taken against explicit orders, having produced these attacks. There was no neurotic element in the case.[1]

Finally, I shall merely refer to tetany and to tonic and clonic convulsions occurring with dilatation of the stomach, as described by Dr. Einhorn. The causes of these attacks are still in dispute, anto-infection and other factors being given. It suggests itself to me that in part we may offer as an explanation a sudden *acute hyperdistention occurring in a chronic dilatation* of the stomach, as an etiological factor, and as the attacks are acute, I have placed these cases under the heading of acute dilatation.

ETIOLOGY OF CHRONIC DILATATION OF THE STOMACH.

Nothnagel holds the view that some of our cases of dilatation of the stomach have existed for many years and that it may be traced back to improper methods of feeding at an early period of life.

In this regard, I wish to call to your attention the average capacity of the stomach in infancy, as described by Dr. L. Emmett Holt: at birth, one and a half ounces; at three months, four and a half ounces; at six months, six ounces; at twelve months, nine ounces. In the act of nursing, the baby works for its dinner, so to speak, and the process is slow. On the other hand, milk is taken from the nursing bottle with greater ease and with much greater rapidity and the infant is often assisted by the fond mother, or nurse, by "tipping" the bottle to an extreme degree. You will appreciate that I am now speaking of the mere mechanics and not of the quality of the food. In addition, I have often seen a nine-ounce bottle of milk given at one feeding to a baby six months old, or even younger, when the stomach capacity is much less than that of the milk bottle. Fortunately beneficent nature again intervenes in most cases and the stomach ejects the excess of food. Overfeeding and chronic indigestion are causes of dilatation of the stomach in infants and in young children and a great responsibility therefore rests upon the family physician, in the proper regulation of the food of the young patients entrusted to his care. Rickets is another causative factor in the production of dilatation of the stomach.

In young children, as I have already called to your attention, acute dilatation of the stomach may be productive of convulsions. Holt believes *intestinal putrefaction exciting convulsions* in children to be an important etiological factor in the production of epilepsy. Acute dilatation of the stomach with resulting convulsions, I believe to be a strong factor when frequently repeated in producing the convulsive habit, and some cases of epilepsy can certainly be imputed to this. In fact this will explain some hitherto obscure cases. Moreover, chronic dilatation of the stomach is, in itself, one of the causes of intestinal disturbances and of intestinal putrefaction.

Personally, I have no patience with the term "idiopathic epilepsy," believing that this is merely a confession of ignorance.

Among other etiological factors of chronic dilatation of the stomach are chronic gastritis, atonia gastrica and the "rapid bolting" of food. The latter frequently occurs among patients suffering from nervous derangements and is often a cause of gastric disturbances and of dilatation. On the other hand, dilatation of the stomach, with accompanying intestinal putrefaction are in turn frequently etiological factors in the production of nervous conditions. Spasm of the pylorus due to an ulcer and benign and malignant stenosis of the pylorus are additional causes of chronic dilatation of the stomach. With such dilatation there may be chronic gastritis, hyperchlorhydria (hyperacidity), mold in the stomach, hypochlorhydria (diminished acidity), achylia gastrica, or marked fermentation. Personally, I only practise lavage in cases with chronic gastritis with the production of excessive mucus, or where there is much retention of food with fermentation. I believe that stomach washing is too often overdone. Calcined magnesia with bismuth subnitrate for the mucus; resorcin for the fermentation, at times combined with bismuth, or benzoate of soda, as an alternative and olive oil in cases of benign stricture as a palliative, are of value. Each case should receive the treatment appropriate to the existing condition. Hygiene, diet, massage, electricity (intragastric preferably at times) and proper regulation of the bowels are of value. Hydrotherapy will often be found useful to tone up the general condition. I believe that the domain of surgery should be somewhat enlarged, for example, in some cases of gastroptosis and stomach dilatation and that a certain class of cases of chronic gastritis with marked dilatation and excessive production of mucus, which do not yield to prolonged treatment, might receive benefit, from proper drainage by gastro-intestinal anastomosis. I have in view one such case on my service at the West Hospital.

GASTROPTOSIS.

In speaking of gastroptosis, it is not my intention to describe typical Glenard's disease, enteroptosis, gastroptosis and nephroptosis, with the

[1] I have recently had under observation a case of rheumatic endocarditis, complicated with sudden attacks of tachycardia—the pulse running from 210-250 per minute. Careful observation demonstrated that these attacks were due to acute dilatation of the stomach from overdistention with gas. These attacks have been entirely eliminated under proper diet and the administration of resorcin.

symptoms as given in the text-books, but to refer only to those cases which vary from this fixed type so familiar to you all. There may or may not be nephroptosis, and enteroptosis in some cases cannot be detected by the ordinary methods of physical examination. Ptosis of the stomach, however, is present and, of necessity, enteroptosis accompanies it. The symptoms point chiefly to the stomach.

Hyperchlorhydria (hyperacidity) hypochlorhydria (diminished acidity) or achylia gastrica may all occur in gastroptosis. This is also true of dilatation of the stomach and hence the determination of the position of that organ, in order to secure the best method of treatment, is of great importance. Transillumination of the stomach I consider the most scientific method of differentiation between these conditions.

The question has arisen in my mind as to whether the ptosis of the intestines invariably precedes the descent of the stomach, as is described by Glenard, and whether in some cases of chronic dilatation of the stomach the ligaments may not gradually stretch and ptosis of the stomach follow, as a primary condition, and enteroptosis be the sequel. In Case XXIX. an excellent picture of the stomach was secured and the pyloric end was clearly seen. The lesser curvature had lost its relation to the diaphragm, but just barely so, the stomach was dilated and no nephroptosis or enteroptosis could be detected. The change in position of the lesser curvature constituted a gastroptosis, slight as it was. I have seen two similar cases and these facts are certainly suggestive.

Furthermore, in gastroptosis, I believe we have the chief etiological factor in "mucous colic." Ewald has pointed out that ptosis of the colon frequently exists in this condition and Einhorn has demonstrated that gastroptosis is present in a large percentage of cases of "mucous colic," as is also achylia gastrica. Mucous colic is present also in many cases of Glenard's disease. Mucous colic is not present in all cases of gastroptosis, any more than is hemorrhage in all cases of typhoid fever. All cases of mucous colic are neurasthenic, but all cases of neurasthenia do not suffer from mucous colic.

On the other hand, there must be an underlying cause both for the neurasthenia and the mucous colic—since these two constitute, I believe, a "vicious circle" and react on each other.[1] As far as my own experience is concerned, I have been able to demonstrate gastroptosis as an etiological factor of mucous colic. The abnormal secretion of the stomach undoubtedly aggravates this condition.

It would seem that the ptosis of the intestines, which of necessity accompanies the gastroptosis and the resulting changes in the caliber of the lumen of the gut at various points, fully explain the cramp-like effort to expel the mucus and the tubular-cast shape of the mucus which we see at times. Furthermore, injections of olive oil appear to relieve the attacks of colic, just as it does given by mouth, in the case of stenosis of the pylorus. I do not believe the mucous discharge is due to a true inflammatory condition, but to changes in the circulation due to the abnormal position of the intestines. Where there is a narrowing at one point there must of necessity be a dilatation and congestion in the intestine above it.

I believe that adhesions, rectal obstruction, or irritation and other such causes given by our authorities, are merely accessory factors in the vicious circle.

During the acute attack, rest, antispasmodics, such as asafetida and light diet, as suggested by Dr. Thomson, are of value. Later, small doses of castor or olive oil, given internally, have an excellent effect. High enemata of olive oil are of service, alternating with irrigations by the Kemp tube of normal saline solution, weak flaxseed tea, or gum arabic solution (ʒii. to ʒiii.) to the quart of warm water. I have had excellent results from the injection of carbonic acid gas, as advocated by Dr. Achilles Rose. I do not believe in the immediate "ballasting" the intestines with coarse food, as advocated by some authorities, but agree with Dr. Einhorn that the diet should depend on the condition found in the stomach. The patient should be well fed, however.

I invariably apply abdominal support in cases of "mucous colic," and have always found relief therefrom. This is further suggestive of the gastroptosis and enteroptosis. Rest treatment is of value in some cases, with hydrotherapy. The bowels should be regulated and nerve tonics administered—change of climate is, at times, beneficial.

As to the general treatment of gastroptosis, we may sum up as follows: (1) Correction of the derangement of the stomach by appropriate *diet* and *medication suited to each case.* A careful analysis of the stomach contents should be made, and the motor functions noted; (2) regulation of the bowels; (3) mechanical support, to increase the intra-abdominal tension, such as (*a*) silk abdominal supporters, those manufactured by Stohlmann & Pfarre, I believe to be excellent; (*b*) bandaging, such as by the Van Valzah-Hayes method; (*c*) Gallant's corset; (*d*) Rose's adhesive plaster belt.

Regarding the abdominal belt of my friend, Dr. Achilles Rose, I may state that I have seen some brilliant results from its use. For example, I have noted a complete disappearance of hyperchlorhydria (hyperacidity) and a return to normal conditions, as a result of the mere mechanical support alone. It affords a support[1] to the organs and allows a return to their normal functions, and there will frequently be increase in weight under this method. I think one can never claim to replace

1 To further substantiate this view, I have under observation a patient with typical attacks of mucous colic, which began only two months ago. These commenced a month after confinement. She has enteroptosis and gastroptosis, due to insufficient support of the abdomen after the birth of her child. The attacks began a month after she was confined. She is not neurasthenic and is only nervous at the time of her attack. This is certainly significant.

1 Recently at my clinic at Wards Island, Dr. Graham-Rogers transilluminated a stomach before and after the application of Rose's belt, and found the stomach in this case to be elevated four inches, with the belt applied.

the ptosis, but the general tone is improved and correspondingly the symptoms. The advantage of the Rose's belt is that it cannot slip and become displaced. If a patient objects to any of the most satisfactory material yet in use. It is looser in texture than the other plasters and the sweat readily evaporates through it. It can be worn longer and with practically no irritation. It

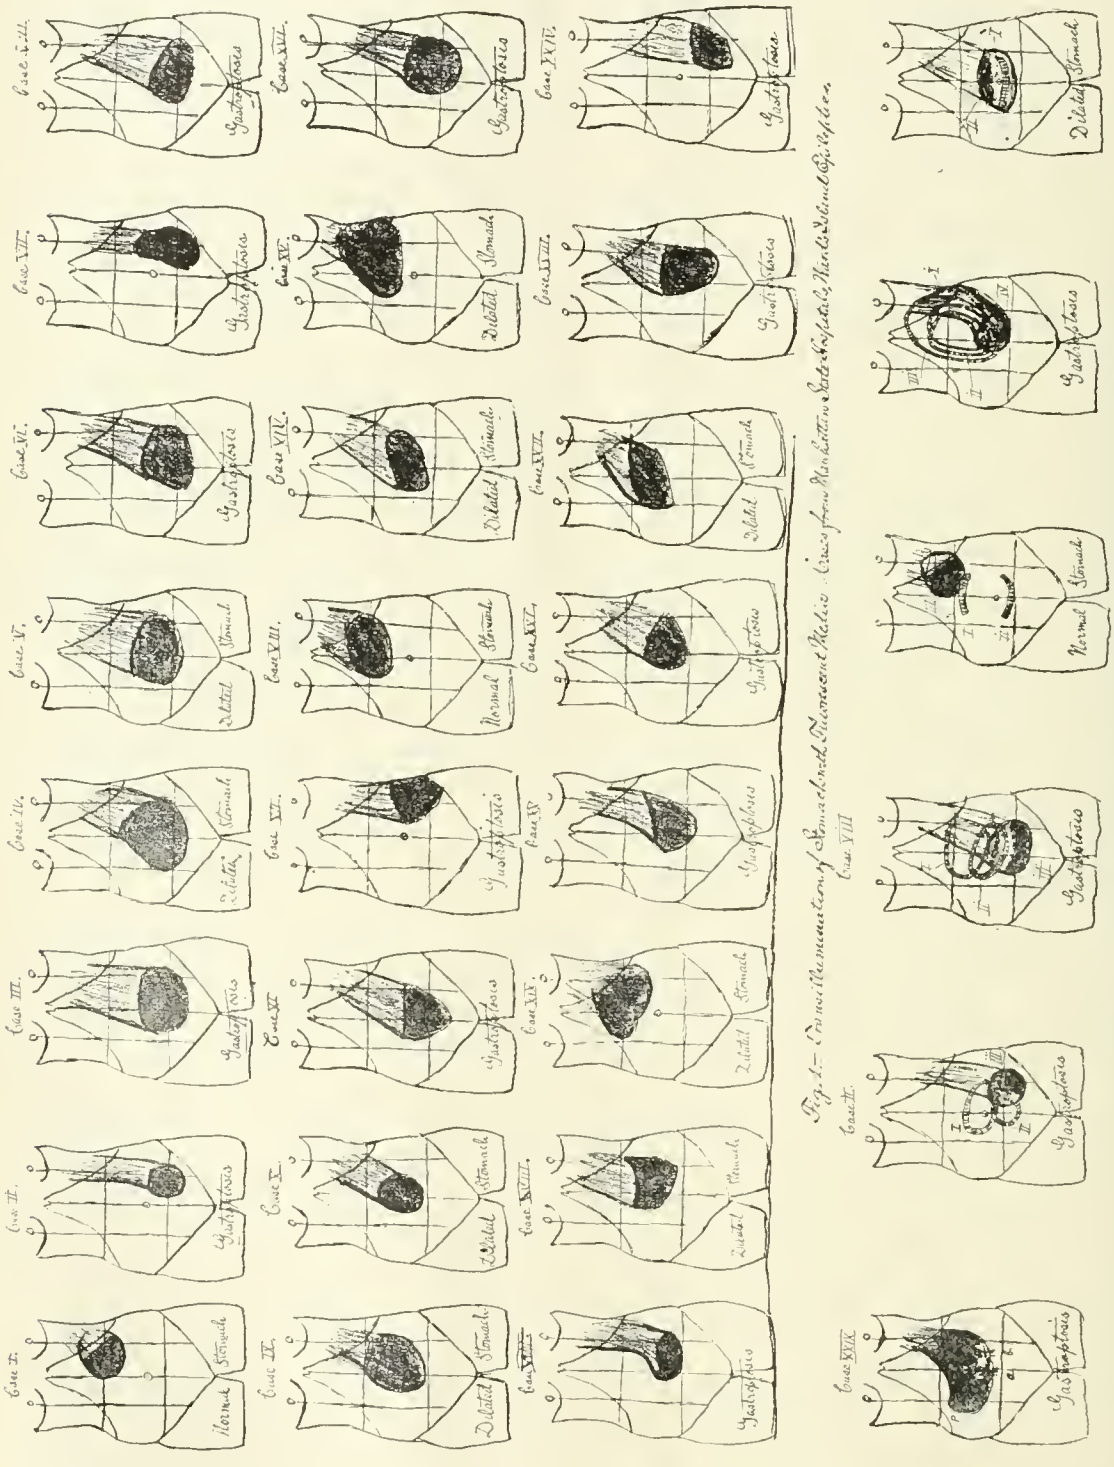

Fig. 1.—Demonstration of Stomach and Movement Ratio. (Kemp from Manhattan Medical Register, Nov. 15, 1898.)

Fig. 3.—Conservative Method of Treating the Ptosis of the Stomach.

its features, it can be readily explained that it is placed there as a splint is applied and objections are thus readily overcome. I have employed recently for this belt, rubber plaster on moleskin, manufactured by Johnson & Johnson, and find it is superior to the ordinary rubber adhesive and even to the zinc oxide plaster.

I wish to state right here, that the question of abdominal support and the various methods to secure it, I have investigated with a perfectly open

and unprejudiced mind and I do not hesitate to say that I now employ the technic described by Dr. Rose, believing it to best fulfil the indications. On the other hand, some of my medical confrères totally discard abdominal support and rely on massage and on exercise to restore the tone of the parts. In some cases of gastroptosis, we may endeavor to secure our results by "putting on fat," by means of the rest cure and selected feeding. In this event, I cannot recommend too highly the treatment of my friend Dr. John Russell of the Post-Graduate Medical School, such as he follows in cases of tuberculosis, and which is doubtless familiar to you all. I believe that this has a great future in the treatment of certain cases of gastroptosis.

Having concluded my observation on dilatation of the stomach and on gastroptosis, I will present some drawings of forty cases from the Manhattan State Hospitals, Ward's Island. Space only allows me to show some of these illustrations.

These demonstrate the position of the stomach in epileptics recently examined. The anatomical regions were marked out in blue pencil on the abdomen of each case and during transillumination of the stomach, the outlines were drawn in colored pencil. These markings were redrawn directly from each subject on paper stamped with a special instrument, giving the anatomical regions. The results secured were as follows: Females, total number, 34 cases; gastroptosis, 16; dilated stomachs, 16; stomach in normal position, 2. Males, total number, 6 cases; dilatation of the stomach, 5; stomach in normal position, 1.

The motor functions of the stomach and the analysis of the gastric contents were made with all these patients. These factors were considered in making the diagnosis. There was abnormal secretion in the stomachs occupying the normal position. These data are certainly suggestive.

Comparative Methods of Locating the Position of the Stomach.—I shall first briefly refer to the position of the patient. In the dorsal position the abdomen is most relaxed; flexing the knees and thighs increases this relaxation. The percussion note is rendered more distinct by opening the mouth and percussion of the stomach should preferably be made from above downward. The liver, spleen, intestines and kidneys should also be carefully examined. On the other hand, the stomach with the patient in the dorsal position falls somewhat away from the abdominal wall and in this regard is not as easy to map out. The position of its contents, for example, when water is administered for the purpose of locating the stomach, is not as favorable for percussion as when in the standing position. As a demonstration of the fact, I have administered a pint of fluorescin solution with the patient lying on the back, inserted the light and endeavored to transilluminate the stomach, with no satisfactory result. As the shoulders are gradually elevated, the outline of the stomach becomes more visible until, finally, excellent results are secured in the sitting and especially in the standing position. In muscular subjects, however, the objection can be made that the walls of the abdomen are more tense when the patient is upright and hence percussion is more difficult.

When employing percussion, therefore, it is my custom to examine the patient in the dorsal, semi-oblique and standing posture, if possible, and to form an opinion from the combination of the three methods.

At this point, I wish to speak of the changes that occur in the position of the stomach due to the administration of food or water. In our works on anatomy and diseases of the stomach the statement is made, that the empty stomach lies for the most part beneath the ribs on the left side, extending a short distance below their border; when partially filled it descends midway between the ensiform process and the umbilicus, and when full, to within a few finger-breadths of the umbilicus. Now, this is true when the patient is in the dorsal position, since the suspensory ligaments of the stomach are then relaxed, and as the organ fills up it gradually gradually gravitates downward. In the standing position, however, the stomach, even when empty, descends to the full length of its suspensory ligaments at once, and its lower border is practically at a constant level, or within about an inch of the same, whether the organ be full or empty. I am aware that this statement will excite immediate dissent from many of you, but it is capable of easy proof. For this purpose, I devised a simple instrument known as the "stomach whistle" (Fig. 2).

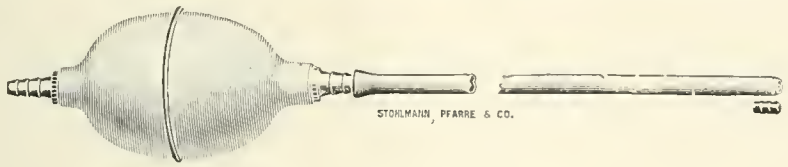

Fig. 2. Dr. Kemp's Stomach Whistle.

This consists of a rectal tube of small caliber, with a whistle in the end. To the other extremity is attached an ordinary stomach aspirating bulb without valves. The tube is inserted, the finger, placed over the open end of the bulb and a single bulb full of air is forced into and aspirated out of the stomach, by rapid and short intermittent contractions. This entirely eliminates the possible chance of distending the stomach with air and the organ remains practically empty. A stethoscope is placed over the abdomen and the point of greatest intensity of sound is marked by a cross with a colored pencil. The tube is pushed in and

out and the various points of sound are marked, the lowest is the lower border of the stomach. The ear, of course, can be applied in place of the stethoscope. Transillumination of the organ was then performed and the lower margins absolutely corresponded. This is also a further evidence of the accuracy of transillumination, as well as of the value of the stomach whistle. Space will not permit in this article to exhibit all the drawings shown at the meeting, but Case XXIX. (Fig. 3) demonstrates the above statements. Five observers located the lower margin of the stomach by means of the stomach whistle at *a* and *b*, on the same transverse line. Transillumination demonstrated their accuracy.

I am perfectly cognizant of the method of administering water and then blowing air into the stomach through a tube—but the "bubbling sounds" only give the level of the fluid and not accurately the lower margin of the stomach. The whistle is therefore of value in this regard, though it will not necessarily differentiate between dilatation and gastroptosis.

Other Methods of Locating the Position of the Stomach.—Various methods were tried on each individual case, as a basis for comparison, and, as a check, transillumination of the stomach was employed as the final procedure in every case. The results were drawn at the time with colored pencil on every patient and then transferred to drawing paper. Fully twenty-five or thirty physicians have examined these cases at my clinics and the results are not those of a single biased observer.

1. *Inspection.*—An abdomen, concave above, convex below, a sulcus in the median line and bulging in the inguinal regions, is suggestive of gastroptosis. However, I recently observed a simple dilatation of the stomach with these conditions existing. Observation of the peristaltic movements is often of value. Some claim that by mere inspection of the abdomen that they can locate the position of the stomach. We tried this method many times and without success.

2. *Inflation with Carbonic Acid Gas.*—This may be obtained by the administration, separately, of the ingredients of a Seidlitz powder, or preferably, by giving sodium bicarbonate and tartaric acid in separate solutions. So often did we fail by this method that I do not present drawings of these experiments. The method is disagreeable for the patient and it is impossible to regulate the quantity of gas.

3. *The Administration of Small Quantities of Soda Bicarbonate and Tartaric Acid With the Patient in the Standing Position.*—In some cases one can approximately map out the lower border of the stomach, by listening to the "sizzling sounds" with the stethoscope. This may at times be serviceable.

4. *Inflation of the Stomach With Air.*—This method is advocated by many authorities. One can attach to the stomach tube a bulb which has been previously tested, by noting how much water each compression of the bulb will displace. By this means we can fairly definitely measure the quantity of air employed, though there is some escape about the tube and often into the intestines. This method, however, may be a cause of great discomfort, often overdistends the stomach, so that we do not obtain its true dimensions and it may even be a source of some danger.

On many occasions what was apparently stomach-becoming to the eyes, protuberant on the abdominal wall, was proved by transillumination to be intestines forced out forward and laterally by the stomach. By inflation with air, a diagnosis of dilatation of the stomach was thus made which proved by transillumination to be gastroptosis; for example, Case II, in Fig. 3. I is position found by air inflation; II, by water inflation; III, by transillumination; also in Case VIII, in Fig. 3.

Let me say right here that I found inflation with water next in efficiency to gastrodiaphany. Water inflation, however, will fail at times, as I shall shortly demonstrate. On the other hand, I have had some successes with air inflation in detecting dilatation of the stomach, whereas it has frequently failed in gastroptosis, the intestines being dislocated and simulating the stomach, as in Case II, Fig. 3.

Some authorities claim that by dilatation with air and placing the patient in a good light, they can secure a shadow of the lesser curvature and differentiate between dilatation and gastroptosis. In subjects with much adipose tissue, or with thick abdominal muscles, I hardly see that it can be practical. So far I have not seen this method successfully applied.

5. *Simple Percussion.*—This method failed to locate the correct position of the stomach in a considerable percentage of cases. The examination was made both in the dorsal and standing position; with the stomach empty, and after the administration of a single glass of water. As a demonstration illustrating these features I can only submit here Case I, in Fig. 3. I and II show the upper and lower borders of the stomach both in the dorsal and standing position as apparently demonstrated by simple percussion, the diagnosis being "dilated stomach." III shows the true position of the stomach as found by transillumination; stomach in the normal position.

6. *Auscultatory Percussion.*—This method frequently fails. (See III, Case XVII, Fig. 3.) The stomach was apparently a simple dilatation—when actually by transillumination it was proved to be a case of gastroptosis.

7. *Reichmann's Auscultatory Percussion Rod.*—This consists of a short ivory rod, with circular grooves and intervening projections, somewhat like the handle of a large ivory knitting needle. The rod is pushed firmly down over the stomach at a right angle to its surface (in a vertical line to the abdomen) and is gently stroked with the finger. The stethoscope is applied over the organ and the "pitch" carefully observed. When the rod passes beyond the limits of the stomach a change in "pitch" is observed. It is claimed that the boundaries of the organ can thus be mapped

out. Case XVII, Fig. 3, serves as an illustration, I, representing simple percussion, dorsal position, with the stomach empty and also after the administration of a pint of fluid; II, auscultatory percussion with Reichmann's rod, under the same conditions; III, simple auscultatory percussion. All these show dilatation of the stomach; IV, transillumination of the stomach shows gastroptosis, which is correct.

8. *Inflation of the Stomach with Water.*—This method seems a fairly good one, in fact I consider it, next to transillumination, the best technic to employ when we desire to map out the position of the stomach. It is much easier to differentiate between the dulness, which we thus secure, and tympanites, than it is between different degrees of tympanites. In all, a pint to a pint and a half of water should be given in divided doses. In case XIV, Fig. 3, I represents the lower margin of the stomach thus mapped out; II, the area of transillumination. They practically correspond. In some of our cases inflation with water failed to give us correct results, however.

9. *Inflation of the Intestines with Air.*—No accurate results can be obtained—and great discomfort to the patient results.

10. *Inflation of the Intestines with Water.*—This method is painful, I believe inaccurate, and before sufficient water is injected, it is ejected.

11. *The Ideal Method to Locate the Stomach Is by Transillumination.*—Originally devised by Dr. Max Einhorn.[1] Subsequent laparotomy on the living subject, experiments with the cadaver and the stomach whistle all demonstrate its accuracy. For your benefit, I show you this evening both the Einhorn and the Lockwood gastrodiaphane and the battery with rheostat, made by Stohlmann & Pfarre. It is possible, however, to attach the instrument directly to the cells, though there is some danger of burning out the light. I employ six to eight dry cells, preferably the latter. The Lockwood light possesses the advantage of being very small, easy to manipulate and does not gag the patient. Dr. Lincoln, of Brooklyn, has an instrument somewhat similar. One can readily improvise a dark room by pinning a blanket over the window. The examination should be made on an empty stomach. As an improvement in technic I have of late employed fluorescent media for transillumination. You will find an abstract of this work in a recent issue of the *Post-Graduate* and in the *New York Medical Journal* and *Philadelphia Medical Journal, Consolidated,* February 13, 1904, entitled "Fluorescin in Transillumination of the Stomach." A subsequent description of the experiments will be given in the Medical News, in the near future.

There are three fluorescent media so far found to be of value: (1) Bisulphate of quinine grs. x. in a pint of water. The addition of m. v. of acid phosphoric dilute intensifies its action. The same amount of acid sulphuric dilute may be substituted. The reaction of the quinine solution is, in itself, acid and the fluorescence a very pale violet. Increased acidity intensifies its action and fluorescence disappears if the solution is rendered alkaline. (2) Esculin; this is derived from the *Æsculus hippocastanum* (horse-chestnut), indigenous to Europe. Fifteen grain doses have been used in malaria. One can employ small doses, gr. ⅛ to gr. ½ in a pint of alkaline solution, which gives a blue fluorescence. This preparation is difficult to secure. (3) Fluorescin, phthalic anhydride (5 parts), a naphthalin product and resorcin (7 parts) heated to 200° C. It is a reddish powder, faintly soluble in water with a neutral reaction and practically gives thus no fluorescence; soluble in alcohol and in alkaline media, giving a green fluorescence like liquid opal. It has been employed to detect ulcers of the cornea. It can be secured from Merck & Co., and is extremely cheap. No further literature was obtainable.[1] I therefore injected one to two grains of fluorescin into dogs and rabbits in alkaline and alcoholic solutions, with no resulting effects either physiological or local. Later, assisted by Mr. Ferry, the chemist of St. Bartholomew's Clinic, we further investigated its properties. He suggested to me the addition of glycerin to intensify the flouresence and we found that the hydrochloric acid of the stomach must first be neutralized. The patient should first be given a glass of water (eight ounces) in which fifteen grains of bicarbonate of soda have been dissolved. A second glass of water (eight ounces) is then administered, in which are dissolved the same amount of sodium bicarbonate, one dram of glycerin and gr. ⅛ to gr. ¼ of fluorescin. One to two ounces of lime water may be substituted for the soda bicarbonate. Curiously enough, as we increase the fluorescin in strength, fluorescence diminishes and colorization begins. By means of fluorescent media, I have found it possible to transilluminate the stomachs of fat subjects, that was formerly unsatisfactory, to examine for tumors and the location of the stomach with greater accuracy, and I believe that I can fairly state that the brilliancy of the transillumination is increased over one-half.

Radio-Active Solutions.—The relations of radio-active solutions and the X-ray to fluorescence interested me greatly. Incidentally, I may say that, as a matter of scientific accuracy, I suggested the infusion of radio-active normal saline solution into animals and also its hypodermic use. We performed these experiments at the College of Physicians and Surgeons, assisted by Dr. C. T. Graham-Rogers and by Mr. J. T. Hoyt. I must say that I could see absolutely no results from the standpoint of physiological medicine and from our researches so far, I feel that radio-active solutions have no therapeutic value whatsoever. I believe that this is the first infusion of a radio-active solution that has ever been performed. There were no physiological results from the infusion, or any changes of heart action and respiration, beyond

1 Laparotomy, by Dr. Robert H. M. Dawbarn, on a case of gastroptosis, transilluminated with fluorescin, at the Manhattan State Hospital, West, Wards Island, has recently demonstrated the absolute accuracy of the method.

1 Since reading this paper, some interesting data have been published regarding the local effects of fluorescent media in diseased conditions.

those of the infusion of a normal saline solution. I show you tracings taken from this animal—the manometer being attached directly to the carotid artery and infusion given into the femoral vein. I now present for your inspection the living dog thus operated upon three days ago. You will note that the wounds are healing nicely and that the animal is in good condition. As to the value of radium, that is a different matter.

In conclusion let me say that if by these observations I shall have succeeded in exciting your interest, I shall feel that I am sufficiently repaid.

107 East Fifty-seventh Street.

EXPERIMENTS TO DETERMINE THE VALUE OF COLLARGOLUM AND ANTISTREPTOCOCCIC SERUM IN INFECTED WOUNDS OF THE EYE.[1]

BY J. H. CLAIBORNE, M.D.,
AND
E. B. COBURN, M.D.,
OF NEW YORK.

Seven and one-half per cent. of the blind are made so by injuries to the eye, usually resulting in panophthalmitis, and because of the ineffectiveness of modern methods of treatment, new and more efficient remedies are desired. Up to the present time iodoform has been most used, and with the greatest degree of success, but its method of application is difficult, and the results are not always satisfactory.

Last year the writers made some experiments to determine the value of formalin in the treatment of infected wounds of the eye, but the results did not show any special advantage in the use of this remedy, even though its innocuousness was clearly shown.

The present tendencies to combat diseases by intravascular medication has not been overlooked by the authors, and certain remedies which have been brought to the attention of the medical profession for use in combating various forms of diseases, supposed to be due to streptococcus infection, have been made the basis of experimentation, the results of which are herewith given.

Collargolum was one of the remedies used; it is an allotropic form of silver (colloidal silver) which is soluble in water in the proportion of one to twenty-five, forming a brownish solution. It does not appear to affect the constitution of the blood or lymph when injected intravenously. It is carried to all the organs, but is eliminated rather rapidly. It has some direct bactericidal action and produces a marked and rapid leucocytosis. Because it is quickly eliminated from the body, its administration must be frequently repeated. It has been used with considerable success in septicemia and pyemia, surgical infections, puerperal sepsis, sepsis of infectious diseases, skin diseases, venereal diseases, and certain muscle diseases, including rheumatism, abscesses, cellulitis, and so forth. It is injected intravenously in a one per cent. solution.

The perusal of medical literature at hand does not show that collargolum has been employed in the treatment of eye diseases by intravenous injection. It has, however, been used by inunction, employed in the form of Credé's ointment, in which form it appears to have been quite efficacious. In the collargolum experiments, the eyes of rabbits were infected by injecting two minims of a turbid emulsion of streptococci in sterilized water into the vitreous. On the following day there was pericorneal injection, iritis and exudate, into the vitreous. Treatment was now begun with a two per cent. solution of collargolum injected, in one series of animals, into the veins, and in another series, into the capsule of Tenon. Twenty-five minims of the solution were injected into the veins on successive days, but the inflammatory conditions increased, the iritis became more marked, chemosis of the conjunctiva developed, and a yellowish reflex was visible in the fundus. As the result, a condition of panophthalmitis developed and, in spite of the injection, the eyes were lost.

In another series, the injection of a two per cent. solution of collargolum was made directly into the capsule of Tenon. The injection varied in quantity from five to twenty-five minims. Chemosis was fairly pronounced after the injection, and in one animal the chemosis was so great that the pressure on the eyeball produced a pseudoglaucomatous condition, with ulceration of the cornea, which eventually caused the destruction of the eye. The discoloration of the subconjunctival tissue was sufficient to condemn this method of treatment in human subjects, whether or not the treatment had been successful. The treatment, however, was of no value, and the eyes were lost as promptly as those in the first set of experiments.

Another set of experiments was begun by infecting other rabbits with streptococcus emulsion in the vitreous. Collargolum in 100 minim doses of the two per cent. solution were injected intravenously; the results were not different from those mentioned above. Panophthalmitis developed, the eyes became soft and were eventually destroyed.

Serum.—After infecting a number of rabbits' eyes, according to the method described above, a domestic antistreptococcus serum was employed in another series of experiments. After an inflammatory process had begun this was injected in ten minim doses into the capsule of Tenon. The result was equally disappointing. The purulent process developed into a full-blown panophthalmitis and the eyes were lost.

Antistreptococcus serum was injected in other animals whose eyes had been previously infected. The quantity varied from five to ten c.c., and was injected intravenously. These eyes were destroyed in the usual way. One animal received an injection of serum into the capsule of Tenon, and while the injection was being made from the glass bulb which was supplied with a rubber ball to expel the serum, a small quantity of air was

[1] Received for publication March 15, 1904.

also injected. The rabbit was placed at one side, and while attention was directed to the treatment of the other animals, the rabbit died. The time was certainly less than five minutes. The autopsy showed a frothy clot in the right ventricle and air in the coronary arteries.

Still another series of experiments with the antistreptococcus serum injected both intravenously and into the capsule of Tenon, resulted in the same way. The eyes were all lost by panophthalmitis.

An examination of the eyes of the animals which were employed in the preceding experiments, a month later, revealed various interesting conditions: in some iris *bombé*, occlusion, softening and pannus; in others, posterior synechiæ, new formation of blood vessels in the iris, yellow reflex from the fundus, minus tension, and pannus.

To determine the value of these various forms of treatment in combating phlegmonous inflammation of the orbit and eyelids, some of the same emulsion which was used to infect the above-mentioned rabbits, was injected through the lids into the orbit. It was found impossible to produce any inflammatory reaction by the use of this method of infection, and hence, experiments to that end were abandoned.

For another series of experiments, we were kindly supplied by Parke, Davis & Co. with a liberal quantity of their antistreptococcus serum, and by Schering & Glatz, with a quantity of Aronson's antistreptococcus serum. Rabbits were infected as before by injecting streptococcus emulsion into the vitreous. These experiments were carried on in three ways: (1) by injecting the serum into the capsule of Tenon, (2) by injecting it into the capsule and into the subcutaneous tissue, and (3) by the hypodermatic method alone. The quantity injected into the capsule of Tenon was generally about 30 minims: with the combined method the injection into the capsule was 30 minims and into the subcutaneous tissue of the neck, 10 c.c.: in the subcutaneous method alone, 10 c.c., were injected each time. The experiments were failures in every instance, and as it was thought that the inflammatory process made too great headway in twenty-four hours, which was the usual time for commencing reaction after the initial infection, the injections were made from twelve to eighteen hours after the primary injection of streptococcus emulsion. Without exception, no difference could be noticed in the course of the disease, and the treatment seemed to be without any favorable action to inhibit the inflammatory process. Considerable hopes had been raised that Aronson's serum would prove effective in the treatment of these animals, as Aronson's serum is the one which has been most successful in the treatment of infectious diseases in animals.

A review of the ophthalmological literature reveals only one instance where serum was employed in the treatment of eye diseases. Attanasio (Archivio di Ottalmol., vol. ix., Jan., 1902, p. 241) employed Marmorek's serum in the treatment of eye diseases and he found the serum treatment quite effective. The serum relieves the pains after a few hours. If the injection is made at the commencement of the purulent infection and in sufficient quantity, it neutralizes the toxines taken into the circulation, it diminishes the virulence of the streptococci and other microbes (which produce suppuration) by increasing the defensive powers of the tissue. He recommends it as a preventive of postoperative infections, but in such cases it ought to precede the operation.

Remarks.—The intravenous injection of certain remedies, such as bichloride of mercury, formalin, protargol and other antiseptics, has shown that many of them act favorably. Certain ones, however, depress the system to such an extent (whether by affecting the elements of the blood or by other poisonous action, is immaterial in this paper), that, in experimental cases the animals which receive maximum non-toxic doses die more rapidly than animals not so treated.

While the writers are well aware that experiments on animals are not conclusive, they certainly afford an indication, at least, of the action of various medications on the human system. In view of the fact that collargolum has been used with great success in the treatment of various septic processes in human beings, conclusions drawn from these experiments should not stand in the way of the treatment of similar ocular infections in human beings by collargolum.

It is known that treatment directed against encysted collections of pus, are not so favorably acted upon by these methods as general infections are. In the eye, the processes are limited by the coats of the eyeball, and it is not impossible that the conditions are comparable to a pus collection elsewhere. We know that exudative processes in the eye are but slowly influenced by any form of treatment, local or general. So far as these experiments go, there is nothing to indicate that collargolum or serum should not be employed in the treatment of certain ocular diseases in human subjects.

Local treatment by subconjunctival injections of collargolum solution are certainly not to be recommended. Whether these remedies act by leucocytosis, by antiseptic action (as in the case of collargolum), or by some inhibitive process (as in the use of serum), is as yet unknown. There seems to be no good reason why serum treatment should not be tried in all forms of purulent eye diseases. It has been found successful in the treatment not only of pure streptococcus infection, but also of such infections mixed with staphylococci.

Of course, not all infectious processes in the eye are caused by the streptococcus. The staphylococcus and the pneumococcus have both been found in purulent diseases of the eye, but in view of the generally accepted idea that streptococcus infections are generally fatal, the use of antistreptococcus serum, being harmless, may be of benefit, even though selective in its action.

Some writers claim that all streptococci are alike, while others claim that there are various forms of these bacteria, and seem to prove their assertion by *agglutination* methods.

It is found that the preparation of efficient sera requires certain methods, it being necessary in general that the sera be prepared from virulent cultures. Some hold that the cultures should be passed through intermediate animals, while others claim that, by so doing, the specific and selective agglutination action of the serum thus prepared is not obtained, and prefer serum directly prepared. An interesting fact is that the blood of diabetics seems to impair the action of certain sera.

The reasons for failure of the action of antistreptococcus serum may be ascribed to the variability of the streptococcus; to the fact that few septic processes are simply streptococcus infection alone, but are more often mixed; to the improper preparation of the serum from cultures indirectly, cultures not taken from cases of a similar kind for which the remedy is applied; or finally to the application of serum in insufficient quantity or after the process has become so far advanced that any treatment would be ineffectual. It may not be impossible that the serum deteriorates rapidly after its preparation. In certain experiments on animals it has been shown that the doses of serum must be enormously increased the longer the treatment is begun after the primary infection. In view of the fact that any treatment of infectious processes in the eye is so unsuccessful, the writers recommend the employment of serum in the treatment of such cases.

A word of warning should be given in regard to the use of serum containers now generally placed on the market. The unfortunate result of death by air embolism after subconjunctival injection of serum from one of these containers supplied with a rubber bulb, makes it necessary to recommend the exercise of considerable care. The more recent serum receptacles, prepared or manufactured in the form of a glass syringe, seem to avoid any possibility of death from air embolism.

Conclusions.—(1) Collargolum is ineffectual in preventing the spread of purulent processes in the eyes of rabbits, whether used intravenously or by injection into Tenon's capsule. (2) Antistreptococcus serum does not appear to exercise any favorable influence on purulent processes in rabbits' eyes.

Punton Sanitarium.—Dr. John Punton, Superintendent of the Punton Sanitarium or Home for Nervous Invalids, at Kansas City, Mo., is adding a large addition to the sanitarium building in response to an increased demand for accommodations by patients. There is also being built a large extension to the verandas, which will be used by the guests for places of recreation. The management of the sanitarium highly appreciates the support received from the medical profession, and has great confidence in the continued success of the institution.

PUERPERAL SEPSIS.[1]

BY SWITHIN CHANDLER, M.D.,
OF PHILADELPHIA.

This subject has been the theme upon which the poet and the scholar have vied with each other in giving warnings and admonitions, not always wise, but nevertheless, sincere. To rehash the history and words of authors would be only to tax one's patience, and add nothing new. Therefore, we will not speak of the cause, symptoms, and ancient history of this puerperal sepsis, but try to present to you views which it is believed will be new in regard to the surgical treatment, and the value of the study of the respirations in this trouble.

In my judgment it is a subject that is open to new suggestions, because it is acknowledged that the present treatment of puerperal sepsis is not all that could be desired. John Clark, speaking at the County Medical Society in Philadelphia, made the statement that hysterectomy had failed to fulfil this mission, and as this is the last operation brought forward, it cetainly leaves us in the same position in which we were before its introduction.

Knowing this to be the case, we were stimulated to endeavor to aid in the solution of this problem, which in so many cases not only causes the physician to lose his case and family, but so often injures his reputation. The operation which we suggest is new to me, and if it has been done before we performed it, it is unknown to me.

Pryor, of New York, read a paper in Philadelphia, we understand, upon this subject, but I did not hear the paper, and only a part of the debate, so I know not his position in the matter. What we have been doing for the last six years in addition to the general treatment, etc., so well known, is the following: Make an incision posterior to the cervix in the posterior vaginal wall; then pass a pair of long blunt-pointed forceps, slightly curved, in the cervical canal, up into the cavity of the uterus; puncture the posterior wall in the center near the top of the uterus. Then introduce with two fingers a piece or strip of iodoform gauze through the posterior vaginal opening previously made, clasp the gauze with the forceps and drag it through the uterine wall and out through the vagina. Repeat this by puncturing the uterus on each side, but posteriorly and just about the middle of the body, drawing the gauze through in the same manner as in the first attempt.

Thus, one will see, we treat the uterus as a thoroughly infected organ deserving heroic treatment. We feel that we have been and are justified in this procedure, and will report four cases from a list of twenty so treated, and made deductions from these, being well aware that before this is proven to be the best treatment, many cases must bear testimony:

Case I.—Patient, thirty-two years old, mother of two children. Supposed to be in perfect health

[1] Read before the Northwest Medical Society of Philadelphia, March 1, 1904.

previous to confinement. Child born on March 2, 1898. On March 4, forty hours after labor, patient had a chill, temperature rose to 104° F., pulse 130, respiration 38. March 5, temperature 105° F., pulse 140, respiration 40. Face pinched, anxious and flushed. Lochia scanty and somewhat offensive, general perspiration over entire body.

Same evening cleaned bowels with stimulating enema. Gave tincture digitalis, 10 m., hypodermically, and proceeded to etherize case. After most careful preparation, curetted, removing piece of placenta, uterine lavage with ten quarts of plain sterile water, and one quart of normal salt solution, opened posterior vaginal wall, investigating with finger, tubes, ovaries, etc. Then passed forceps through uterus and withdrew gauze, as before mentioned, leaving same in to drain, thus forming a U of gauze, entering the vaginal opening and leaving through cervical canal and out of vagina. Quinine sulphate 20 grains, given every three hours, as after-treatment.

March 6, patient generally improved. Temperature 103° F., pulse 120, respiration 34. March 7, still improving; temperature 101.2° F., pulse 108, respiration 30. Continued to improve and made good recovery. Drains removed on sixth day after the operation and replaced by uterine and postcervical gauze drainage only. All drainage removed on thirteenth day.

Case II.—Patient twenty-six years old, first child. Normal until birth of child, as by examinations. Labor on July 10, 1900. Was greatly torn in cervix and posterior vaginal wall into uterus. Repaired immediately. Same evening, temperature 104° F., pulse 140, respiration 40. Continued to rise until fifth day, then temperature 104.2° F., pulse 124, respiration 36. Operated upon same procedure, also cutting stitches previously inserted. Sixth day, temperature 103.2° F., pulse 120, respiration 30. Seventh day, temperature 101° F., pulse 118, respiration 30. Continued to fall until twelfth day; all normal, dressings removed and others substituted as before. Recovered.

Case III.—Patient, forty years of age. Mother of six children. Labor began August 15. Was in labor for twenty hours, when version was performed. Cervix and posterior vaginal wall torn. Repaired immediately. Temperature at the end of six hours, 104.2° F., pulse 128, respiration 40. Third day, temperature 106° F., pulse 154, respiration 44. Operated. In addition to operation aforesaid, because of infiltration and swelling of the tubes, ovaries and broad ligament these were punctured and relieved of a yellowish discharge containing many streptococci. Following day, temperature 104° F., pulse 140, respiration 40. Third day, temperature 103° F., pulse 140, respiration 36. Fourth day, temperature 103° F., pulse 120, respiration 32. Fifth day, temperature 102° F., pulse 120, respiration 30. Gradually, with fluctuations, temperature, pulse and respiration returned to normal, and patient made a slow recovery.

Case IV.—Patient, thirty-nine years of age. Married, mother of eleven. Possibly had a right pus tube for many years; time unknown. Craneotomy performed on child Nov. 6, 1902, and child delivered. Mother was horribly lacerated, and as there was so much shock, the physician did not repair the injuries. Posterior fourchette and sphincterani torn through, cervix torn almost up to uterine artery. Great shock followed.

On seventh day after labor, temperature 105° F., pulse 135, respiration 34. Operation and same treatment as described above. Patient was afflicted with a venous thrombus on left side, and was confined to bed for ten weeks, but finally recovered.

One subsequent case upon which we operated died two hours after, but I think the operation was attempted too late. It was on the ninth day, and the woman was in a condition of collapse.

Some Objections.—(1) We will see at a glance that there are certain cases where the mildness of the infection makes this operation unwise. This is admitted, and such operation is not advised. (2) Some will believe it makes another wound, and is therefore another source of infection. (3) Cases like Case I might have recovered upon removal of the placenta. (4) Result in labor.

The first objection is admitted. As to the second, the uterus is generally already infected, and where it is not, experiences up to date do not prove the objection, but rather the contrary, as in Case I. As to the third, cases may and do recover after removing retained membranes, but such cases as a rule are mild infections at the start, but afterward if not removed a genuine infection takes place, and the operation is demanded. Regarding the fourth, results in after-pregnancy and labor are only theoretical.

Briefly for the operation one can say: (1) It is conservative; (2) it is easily performed; (3) it is logical, as it gives drainage to an infected organ and parts; (4) it recognizes a true condition and treats it accordingly; (5) so far it has met with the best results of any method, in my hands.

Because this paper is longer than expected, we will only briefly point out one fact noticed in these cases, and that is the great danger signal in puerperal sepsis is the rapid respiration. Many cases of high temperature and pulse almost beyond belief have recovered, but when respiration runs from 45 to 50 the gravest condition is manifested. In order to demonstrate this, we present a chart for inspection, and you will quickly perceive the rapid respiration, and that it is not in rhythm with the temperature and pulse.

Just when the patient seemed to improve generally (with the exception of a bronchitis which supervened) and in the words of Dr. Cadwalader, the case evidently was recovering nicely, the respiration became rapid. Although the temperature was almost normal, the pulse had returned to a safe condition, the respiration was the only sign that forewarned death. I wish to thank Dr. Edith Cadwalader for the courtesy of the loan of the chart.

VACCINATION AND THE LAW.[1]

BY NELSON G. RICHMOND, M.D.,
OF FREDONIA, N. Y.

At a meeting of a liberal club, the subject of the evening was quarantine. The paper was able and appeared complete. But in the discussion which followed it was evident that from design or otherwise vaccination had not been mentioned. Consequently it became the conscientious duty of a lawyer (who, by the way, was an intimate friend of the reader of the paper), to begin a tirade on vaccination, holding it up to ridicule and vividly picturing the horrible results which follow its practice. The audience was an intelligent one, and it was evident that the antivaccinationist had a popular following.

It happened that at this time the City Board of Health had been enforcing the vaccination law in its relation to the public schools. The willing ones had been vaccinated and the unwilling ones were objecting and opposing the enforcement of the law, with the usual embarrassment to the Board of Health. The State Board said the law must be enforced, and the local board did its very best, with the customary result of exciting animosity and vituperation, and in the end having its provisions evaded by many.

At a meeting of a medical society of two adjoining cities, composed of the physicians in active practice of both schools, a resolution was introduced that inasmuch as scarlet fever was known to be present in one of the towns, the society petition the Board of Health to suspend the enforcement of vaccination, until such time as the city was found to be free from contagious disease. The discussion was very spirited and there was by no means a unanimity of opinion; and while the resolution was lost, it was evident that there were some present who were either lukewarm on the subject or were disbelievers in the efficacy of vaccination.

Smallpox was found in a neighboring city of an adjoining State and the Board of Education began an intelligent effort to enforce the law in its relation to children attending the public schools. The lives of the superintendent of those schools and the Board of Education were not enviable ones from that time on. The opposition organized and gathered within the folds of their banner a very respectable, determined force. Legal counsel was employed and plans were laid to bring action against the superintendent in every case where it could be proven that children had been in attendance upon school without a vaccination certificate. They reasoned that long before the final case had been reached the board, sick and tired of the contest, would drop the matter, and then their children would be admitted without vaccination.

In order to meet this strategy the superintendent, acting under the advice of the board, engaged two of the ablest lawyers obtainable to defend the case.

In the test case the superintendent of schools was brought before a justice of the peace and was convicted of admitting to school a pupil without a certificate of successful vaccination. Defeat was admitted, a necessity by the defense, before the trial was begun. Their only hope was to find flaws in the record for the docket, which when once made and sworn to could not be altered. By diligent search they did find two flaws, so that by bringing these into prominence and by using a peculiar form of review trial, they prevented the case being reopened and won the suit. The prosecutors were really fighting a battle contrary to their convictions, to intimidate the Board of Education, which was the real target, from enforcing the law.

The next move of the defense was to delay proceedings until a bill had been introduced and passed by the State legislature to stop all prosecutions that should be begun sixty days after the violation of the act. So strong a weapon did the prosecution wield that this act of the legislature was made necessary to stop further prosecutions.

I will not attempt to defend a law which permits the finding of insignificant flaws to reverse a verdict. I would rather question the wisdom of a law which courted violation.

The Board of Education in a neighboring city recently decided to enforce the vaccination law. Protests began to be made and protestants published their objections in the daily press. Public meetings were held and agitators from neighboring cities came to strengthen the opposition. One-half of the children remained away from school as well as some of the teachers. The Board of Education finally rescinded the order.

These illustrations are given as typical ones of the inconvenience, annoyance and boycott boards of health and boards of education have to endure when they make any reasonable attempt to enforce the law in regard to vaccination in the public schools.

If there is one thing in medicine which has seemed settled, it is that vaccination, skilfully performed, and repeated if necessary, protects from smallpox. And it has been with some surprise and not a little pain that I have witnessed an apparently growing hostility to an act which has saved so many lives. And the question arises, is there not one principle in medicine which is settled for all time? Is it not true that instead of a growing conviction of the truth of the discovery of Jenner there is an increasing number of the laity who disbelieve it: and that these innocents are usually headed by some one who has the degree of M.D. attached to his name?

The Public Health Law says: "No child or person not vaccinated shall be admitted into any of the public schools of the State, and the trustees or other officers having the charge, management or control of such schools shall cause this provision to be enforced."

The Compulsory Education Law, as amended at the last session of the legislature, says: "Every child between eight and sixteen years of age, in

1 Received for publication May 27, 1904.

proper physical condition to attend school, shall regularly attend upon instruction at a school in which at least six common school branches, etc., are taught."

The Department of Public Instruction Rules: "That a child who is not vaccinated is not physically able to attend school."

One law says they must attend school. The other law says they cannot be admitted without vaccination. Some parents say their children shall not be vaccinated, and so boards of education are in a dilemma, whenever they begin the crusade. It has been held by the courts that a child shall not be vaccinated without the consent of parents, and if parents refuse their consent the board may refuse to admit such a child to school. Still the department believes "that a wise and judicious" management of this matter would result in admitting children to the public schools, even though the law as to vaccination had not been complied with, or vaccination had not been successful, only excluding them when the prevalence of an epidemic of smallpox or some other conditions might render this necessary. The department says, however, that this is only an opinion which has no force as an interpretation of the law, and if the Board of Education feel that the provisions of the vaccination law should be rigidly and literally enforced, they must hold that children whose parents refuse to allow them to submit to vaccination are not "in proper physical condition to attend school."

A great deal of trouble arises in interpreting the law in cases where vaccination has not succeeded. Some claim that they have complied with the law when they have been vaccinated, whether it works or not. Others claim that when the vaccination has been repeated and is still unsuccessful, the law has been complied with. A recent decision of the attorney-general of the State of New York says that physical compliance with the act of vaccination fulfils the law whether the vaccination is successful or not. Others, mainly health boards, interpret the law requiring vaccination to mean successful vaccination.

It is customary to class those, in whom the introduction of the vaccine virus is not followed by the different typical stages, as immune. But the conviction has been growing that the immunes are constantly diminishing in number. If vaccination is of sufficient importance to justify the expense and inconvenience, the bark of immunity is a frail one in which to be sailing. How frequently do we find cases resist the second and third attempt at vaccination, only to yield on the fourth or fifth! Yet a health board finds great difficulty in enforcing the act in those cases which choose to protect themselves with this shield.

The amendment in England, known as the Conscience Clause, had always appeared a step backward,—a movement usually experienced in any great reform. It became a law in 1896. A growing suspicion that these convictions were not well founded led me recently to address an inquiry to Dr. John Thomson, attending physician at the Royal Hospital for Sick Children, Edinburgh, Scotland, and a man of unquestioned fairness and ability. This brought the following reply, which I cannot do better than give in the doctor's own words: "The Conscience Clause was inserted in the Vaccination Act, with the approval of such whole-hearted advocates of universal vaccination as Paget and Lister, with the view of lessening the opposition to the measure. They believed that rigorous compulsion would only provoke opposition; that many of those who were against the measure strongly, on the ground of its being an interference with the liberty of the subject, would not oppose it at all if there were a Conscience Clause. It is, I believe, the opinion of the profession that they were right in this, and that the insertion of the Conscience Clause has proved a distinct success. It has removed many of the stronger men from the ranks of those who oppose the measure, so that the field has been largely left to the cranks. The amount of vaccination in England has, I understand, increased materially. In Scotland, fortunately, we have little trouble in such matters. This has always been a well-vaccinated country and antivaccination has never thriven north of the Tweed."

In the face of the beneficent results from vaccination, which I do not need to substantiate, why is it that the opposition in this country is so great? And how can this opposition be met? A business man cannot be on a board of education or a physician act as health officer, when the vaccination laws are enforced, without serious damage to his business. Sometimes the penalty of a conscientious performance of duty involves a sacrifice greater than he or his family can consistently undergo. The answer to the question is apparently easy. The remedy is more difficult.

It is generally admitted that the opposition to vaccination arises from the enforcement of the compulsory law. There is no doubt the law has effected more widespread vaccination than individual option would produce. There is no doubt that in monarchical forms of government, where wages and population do not permit the food, air space and ventilation, which we in this broad country enjoy, compulsory vaccination is essential. But in this "land of the free and home of the brave" people chafe under the restrictions of prohibition and become obstinate under the enforcement of compulsory vaccination. There is no doubt that many oppose vaccination not so much from the fact that they disbelieve in it as that they are compelled by law to undergo it.

Since the introduction of antidiphtheritic serum the case of diphtheria where it is not used is an exception. Notwithstanding the expense, the authorities have made it possible for the very poorest to have the benefit of it. The opposition in the profession has dwindled into insignificance and the knowledge of its value has become so general that a physician's popularity would hardly withstand the effects of losing one or more cases of diphtheria, where it was not used.

Would the introduction of antidiphtheritic

serum have been so rapid and universal, had there been a compulsory law regarding its use?

At the last annual meeting, at Albany, this society had the pleasure of listening to a scholarly paper on "Some Scientific and Practical Aspects of Vaccination," by Dr. P. H. Bryce, secretary of the Provincial Board of Health of Ontario, Toronto, Canada. Dr. Bryce said that opposition to vaccination is due to the fact that the laws are compulsory. He also argued that since the State, for good and sufficient reasons, accepts the responsibility of compelling people in perfect health to be inoculated with a disease, it was the duty of the State to provide qualified public vaccinators who should be empowered to vaccinate systematically: register all infants born; that naturally these men would become experts; would use only the best proven and pure vaccine; and would secure a fund of information which would be valuable. These suggestions are worthy of serious consideration.

The remedy of amending the compulsory vaccination act in the public schools, at the present time, is probably too radical to meet with popular approval in the profession, from whom such a suggestion should come. But I believe it is not too early to agitate and give serious consideration to the question—and it is quite possible that in the full fruitage of time an amendment to the vaccination act may originate in and be promulgated by the army of its friends, rather than by its enemies, who depict in florid colors the horrors of vaccination.

There is another remedy, however, which this paper might suggest, and that remedy is popular education of the laity. Notwithstanding that the centennial of the discovery of vaccination has been passed, and in spite of its acceptance by the civilized world as a preventive of great value, there is very little known of the proof of actual benefits arising from it or of epidemics stamped out by resorting to it.

At the Chautauqua Summer School for 1903 Dr. William S. Bainbridge, of New York, gave a series of lectures before the large audiences there assembled on medical topics with these subdivisions: "The Discoveries of the Middle Ages;" "Progress in Every Age;" "What Has Been Accomplished in Fighting Smallpox."

It occurred to me in reading the admirable presentation of this part of the subject that there were likely to have been many so-called antivaccinationists in the audience who needed their attention called to such recent proof as has been given in the province of Santiago, Island of Cuba, and in the Philippines. This paper suggested that not only were these people far behind the times, in opposing vaccination, but that they might become a menace to society.

The opportunities of presenting medical topics before popular audiences are frequent, and I would suggest that there be a very general presentation of the subject of vaccination. Admitting that there is usually embarrassing opposition to every attempt to enforce the vaccination law, I would suggest that it be enforced with a wise, judicious and, when necessary, firm hand; that duty may be performed, but that opposition may not be needlessly excited; that the question of amending the law, in the course of time, be given earnest thought; that each physician improve every opportunity, giving argument and citing proof that vaccination does protect; and that each individual should willingly submit to it, whenever the presence of an epidemic makes it expedient, or his physician thinks wise, regarding it as a duty he owes the community.

DIPSOMANIA AND ITS TREATMENT.[1]

BY WILLIAM LEE HOWARD, M.D.,
OF BALTIMORE, MD.

Dipsomania I consider a symptom of functional neurosis, the periodic psychic explosions being caused by accumulation of autotoxic material, this being primarily due to an unstable nervous organization allowing faulty metabolism. In individuals born with a neurotic temperament it does not take long for faulty metabolism to enter as a factor in causing inhibitory insanity. Under the conditions of living and the high mental pressure which is the lot of most of those subject to dipsomania, suboxidation is almost constant. Products of suboxidation, alexins, cause auto-intoxication, and in a certain class of neurotics this is demonstrated by an uncontrollable desire for narcotics—alcoholic drinks being those most easily obtained.

It is the existence of this condition—the accessibility of alcoholic drinks—which has thrown a veil of misconception over the morbid impulses of those suffering from periodic psychic restlessness and physical discomfort. It is not the love or passion for alcohol that causes the dipsomaniac to consume such enormous quantities of this narcotic, but because it is the one drug easily and always obtainable; and found amid genial and willing companions. No other narcotic gives the bodily comfort or produces the psychic anesthesia as alcohol in its many potable mixtures, and for this reason it is resorted to with vehemence and avidity when once the paresis of inhibition enters upon its course of a few weeks' duration. This condition I call inhibitory insanity, and its aura is well expressed by Schiller, who suffered from this functional disturbance, when he wrote of himself, "My mind is drawn different ways; I fall headlong out of my ideal world."

As I have elsewhere stated[2], the dipsomaniac is found among the intellectual classes: the physician, lawyer, literary man, artist and musician. One must be able to draw an incised line between dipsomania as a symptom of cortical disturbance, and inebriety, or chronic drunkenness, in order to successfully treat these cases. That this distinction or rather the recognition of dipsomania as a symptom of disease, is not acknowledged by many medical ruminants, is well recognized, but also is

1 Received for publication April 30, 1904.

2 "The Perverts." G. W. Dillingham Company, New York.

Hamlet's remark, that "Virtue cannot so inoculate their old stock that they shall relish it."

Clinically the distinction is readily made. The individual who demonstrates the objective symptoms of dipsomania will be found to be a man of culture and quiet habits. He will go months, and sometimes a year, living an honorable and upright life. He will probably hold responsible positions, and never be seen by his social or business friends in barrooms or lupanar dens. He is most likely to be an individual who has accomplished some great literary work, or perhaps just successfully ended a financial *coup*. At the oncoming of an attack he appears restless, does not sleep, begins to neglect his daily routine, and finally disappears from his customary place of work. He is well aware of the symptoms as they arise, and if he is a methodical man, he will so arrange his papers and affairs as to allow of their neglect for two or three weeks.[1] He knows from experience the power of the nerve storm which is soon to break, and he hurriedly and silently goes to a distant town, or if the storm breaks in all its impulsive fury before he gets away, he hies to a remote quarter of his town, where he remains to the delight of the bums and drunkards—whom he is certain to find—and who live off this individual whose energies are bent to consume all the possible quantity of liquor obtainable. With no direct recognition of self, this ambulent entity exists in an impulsive individual zone until the cortical neurones come again into their own. The recovery takes place immediately, almost spontaneously, and then there is great physical relief and psychic equilibrium: a totally different condition from that seen in the drunkard, who demonstrates all the signs of alcoholism after a few weeks of steady, constant drinking, the drunkard will have delirium tremens, the dipsomaniac mental freedom and physical comfort. During an attack the dipsomaniac, even when he has consumed liquor enough to make two men maudlin, has no difficulty in pronouncing large words or speaking long sentences; there is no evidence of dysarthria as seen in paresis or drunkenness. In this fact we can recognize that there is an overstimulation of energy in certain portions of the cortex, while other symptoms demonstrate plainly that there is partial paresis of inhibitory centers.

The unfortunate victims of this disease are generally those who work at a high and continuous mental and nervous pressure. Mental concentration for weeks or months, the whole nervous organization under forced tension, can only result in exhaustion of nervous energy, and this brings about a lessening of the inhibitory. The neurasthenic's attempt at prolonged mental application ends in mental pyrotechnics, in the class of neurotics I have indicated, the end of mental application is a craving for relief through alcohol, though both classes are suffering from a disease allied to all the other "psychokinesiæ."

The relationship between cause and effect in dipsomania is not yet well established. The microscopical appearances of the brain tissue in the true dipsomaniac has not yet been studied, as all studies, Bevan Lewis' excellent work for example, having been on those of the chronic alcoholic. That continuous attacks of dipsomania cause pathological changes in the brain tissue is undisputed. It all depends on the original inherent strength of the brain how long the downward course takes. Usually some intercurrent disease or tissue degeneration cuts off the man before he has a chance of getting old.

A true understanding of just how the autotoxic substances affect the neurones so as to cause them to functionate abnormally, a clear comprehension of what is meant by neurosis, its histopathology and pathogenesis (Mettler) are necessary before we can clear up many perplexing problems that surround dipsomania. In this disease there is paralysis of inhibition allowing the obsession for narcotics to control the individual. This is due, in my opinion, to temporary disturbances of the cortical cells from toxins, though to what extent, if any, a true organic change has taken place in the receptive center or centers in these cases primarily is always uncertain. But for practical purposes we may say in all these cases that the will runs riotously. It has been generally considered that defective moral control is uncommon, if not impossible, apart from some general but hidden impairment of intellect having a physical basis. Upon this theory Mettler pertinently remarks "that the basis of a true neurosis is a constituent change of some sort in the nerve cells; for a disturbance of function sufficient to be recognized as a disease, with the preservation of normal structure, is a logical contradiction."

The idea that dipsomania is a disease directly inherited has no scientific basis; even as a working hypothesis it is untenable with our present knowledge of heredity. One writer[1] makes the following statement: "Dipsomaniacs are found *only* among persons who have inherited from drunken parents an impellent and periodic desire for strong drink." If the author of this statement had said that dipsomaniacs were found among those of inherited unstable nervous organizations, he would have been nearer the truth. I believe it is a fact well recognized by scientists, that heredity ignores any definite type of disease. The children of "drunken parents" are more apt to be imbecile, epileptic and moral defectives—than they are to be dipsomaniacs. Morbid peculiarities — not diseases — occasionally become in some degree fixed and transmitted in certain families, but it is seldom for more than a few successive generations, for so strong is the principle of return to a normal type that the family is more apt to die out than is this principle to fail. In these cases the law of heredity prevails, but between the laws which are to act and the indefinite variety of forces and circumstances upon which these laws may operate, lies a vast stretch of uncertainty. In other words,

1 See Weir Mitchell's "Circumstance."

1 Berkley, "Diseases of the Nervous System."

a functional disease does not necessarily take the form it had in a past generation. Environment controls the phenomena; this follows the law of material progress; the fundamental cause remains the same, but the effects are governed by circumstances; hence, men are more like the times they live in than they are like their fathers. Environment is a very important factor in deciding the future of a neurotic child. The central nervous system, whatever its natural perfection must be, is extremely responsive to surrounding social conditions, and thus growth processes in it are modifiable in no small degree, hence the condition which social status implies.

If my theory is correct, it is not difficult to outline the rational treatment, but all therapeutic methods are greatly modified by the personality of the physician, a factor that enters here more than in the treatment of any other functional neurosis. The patient must be impressed with the sympathy and understanding of the physician in these cases. The unfortunate victim of dipsomania is generally well versed in the objective symptoms, and none know better than he the fearful struggles and discouraging efforts made to fight the overpowering impulsive demand for alcohol. His wife has pleaded, threatened and blamed; his family physician has told him to use his "will power," his pastor has prayed for and with him, and those few friends who are cognizant of his "periodical sprees," have kindly said he lacked moral control. He, only, realizes how little his case is understood, and silently suffers under the ignorant lash of friends and foes.

When you have been able to abort or shorten an attack in an individual who has been accustomed to weeks of mental hebetude and psychic riot and who has given up all hope of ever avoiding the stigma attached to "a spreer," you have made the first long stride in curing your patient, for it is the knowledge that at least the attacks can be shortened to a day or so, that gives hope and courage. The following case is a good example of my method of treatment:

Case.—M. B., aged fifty-two years; came to me in 1897 with a perfect history of dipsomania. His position was a very responsible one with the United States Postoffice Department. He was obliged to travel extensively. For twenty years he had had attacks of dipsomania at varying intervals, about three or four a year, during which he disappeared from his home or official desk, and remained away on the average two weeks. During this time he would stay in some dark, uninviting rum hole until found by his wife or friends. The recovery was typical, as were the memories of his acts or time. He had but little faith in the various advertised cures, as he had seen the sad results in many of these "graduates."

After explaining my ideas, he immediately cooperated with me, and thus the first difficulty was over. I first put him on a diet that avoided proteids; for it must be remembered than an exclusive proteid diet causes the formation of excessively large quantities of soluble peptones and albumoses, which have an exciting action on the nervous system and constitute a favorable basis for the development of all kinds of neuroses. For a month he was given daily a mild purgative, a natural water, and a Turkish bath twice a week; for *elimination* is the watchword with these patients. This treatment was continued for four months, except that at the end of the first month the purgative was taken but twice a week, and the bath once a week. At the end of four months I was telegraphed to go to him, the message coming direct from him and telling me where to find him. He had been on a long journey, and, upon arriving in Washington, felt a desire for some stimulant. It was not the old rabid impulsiveness, but yet there was a feeling of indecision. He was afraid to move, so sat down in the café of a well-known hotel and wired me. I found him slightly the worse for liquor, but grateful for my arrival, and he gladly went to his home with me. I immediately put him on nitrate of strychnine, gr. 1-20 every four hours, and in forty-eight hours he was himself again. For the suboxidation, which I felt was constant in this case, I taught him deep-breathing exercises. Two years he was under my treatment, having a second attack lasting only two days at the end of the second year. Since then he has been free from any feeling or desire for alcohol.

The amount of strychnine that can be given to these cases when the psychic explosion takes place is astonishing. The drug seems to be utilized in the physiologic economy, for it can be pushed in these patients to what would be an extremely dangerous point in a normal individual, without any signs of intolerance. I keep my patients on this drug for two years or more, having them take 1-30 of a grain t.i.d. for a month, then dropping the drug for six weeks to take it up again for another month. The patients are taught to understand that only by avoiding proteids as much as possible, and by constant watch over all methods of elimination, can they prevent the attacks of dipsomania. I have them thoroughly understand that there is no specific for these attacks: that it is a physiological question purely, and under their own control.

This is a very crude outline of a typical case, but as each patient is a law unto himself, as there are details as numerous as are the varied traits of the neurotic, further remarks would be surplusage. Suggestion in all cases is of great value —especially with those who have become discouraged. Even after you have treated a hundred cases of dipsomania you will find that to be successful each case will have to pass through the alembic of your synthetic experience.

American Neurological Association.—The American Neurological Association meets at St Louis at the Planters Hotel, instead of in the World's Fair Grounds, as originally planned. The sessions will last from 9 A.M. to 1 P.M. daily. A general invitation to attend is extended to the medical profession.

MEDICAL PROGRESS.

PHYSIOLOGY.

The Alcohol Content of the Organs.—That alcohol in small amounts is found preformed in the animal tissues, is the conclusion drawn from his experiments by G. Laudsberg (*Hoppe-Seyler's Zeitsch.,* May 26, 1904). During autolysis the quantity of alcohol does not increase, but it does increase as the result of bacterial decomposition. The origin of the alcohol in the tissues has not been definitely determined. It is probable that it originates in the gastro-intestinal canal, from the decomposition of carbohydrates by means of yeast cells or bacteria.

The Influence of Castration Upon the Thymus.—That there is some intimate relationship between the sexual organs and the thymus, is shown by the experiments of J. Henderson (*Jour. of Physiol.,* June 30, 1904), who found that castration in cattle causes a persistent growth and a retarded atrophy of the thymus gland. Castration has a similar effect in guinea pigs and rabbits. In bulls and unspayed heifers the normal atrophy of the thymus begins after the period of puberty and is greatly accelerated when the bulls have been used for breeding and when the heifers have been pregnant for several months.

Chemical Regulation of the Secretory Process.—The phenomena of life reveal a series of adaptations to the environment. Only recently have physiologists sought to discover the various adaptations of the parts of the organism to changes in the internal environment, to variations in food, and to the manifold changes in the external environment that include climate, altitude, and the host of bacterial infections. The study of the adaptive capacity of the organism has been applied to the secretory mechanism by W. M. Bayliss and E. H. Starling, whose results are described in the Croonian Lecture (*Proc. Royal Soc.,* May 28, 1904). There are two main types that distinguish the complex reactions that make up the life of the individual. The first type of adaptation is dependent on the adaptive growth of cells, and includes those reactions that depend for their production on some special structural arrangement, *e.g.,* the formation of protective tissues and the development of the central nervous system. The second type, which is the more primitive, involves not so much a change in the growth or arrangement of cells as a change in the metabolism of preformed cells or structures. This is chemical adaptation and comprises two groups: (1) Chemical adaptation to the environment, *e.g.,* the mould *penicillium crustaceum,* when grown on calcium lactate, forms invertase only; on starch, however, it produces amylase in addition, while on milk it produces a proteolytic ferment and rennet. The phenomena of acquired immunity belong to this group, and likewise the process of assimilation of food and the adaptation of the animal to changes in diet; (2) the mechanism of internal correlation, effected partly by means of the nervous system and partly by the blood; *e.g.,* the influence of the thyroid gland upon the nutrition of the entire body; and the vasomotor influence of the internal secretion of the suprarenal bodies. The researches of the authors relate to the adaptation of the organism to changes in food and the chemical correlation of the digestive and assimilatory organs. In the mouth is the nervous reactive mechanism controlling the secretion of saliva. The activity of the salivary glands is excited reflexly according to the nature of the substance present in the mouth. The same is true of the reflex secretion of the gastric juice. The secretion of the pancreatic juice is determined by a nervous reflex, initiated by the stimulation of the intestinal mucous membrane by the chyme. Not only is the pancreatic juice poured into the intestine exactly at the time that it is required, but also the composition of the juice varies according to the food, the proteolytic enzyme being increased by a diet of meat while the amylolytic ferment is increased by a diet of starch. This form of adaptation was ascribed by its discoverer, Pawlow, to a species of "taste" in the mucous membrane, in which different nerve endings are stimulated by different kinds of food. Later researches have shown that these pancreatic adaptations may occur even when all the nervous paths from the intestine are cut, as shown by Popielski and Wertheimer, who found that under the above conditions the introduction of acid into the intestine produced a flow of pancreatic juice. The authors confirmed this result. This showed that one is here concerned with a chemical rather than a nervous mechanism. The introduction of acid into the blood did not produce the effects, which were evidently due to some change produced in the acid in its passage to the blood-vessels through the epithelial cells, or to the production in these cells of some substance, which when carried to the pancreas evokes a secretion. This was found to be the case, for rubbing up the mucous membrane with acid and injecting the mixture into the blood stream produced a copious secretion of pancreatic juice. The active substance thus produced in the mucous membrane is "secretin," whose precursor "prosecretin" cannot be extracted by any means. The most active extracts of secretin are obtained from the duodenum. Secretin can be split off from its precursor by the action of acids or boiling water. The power of the acids in this respect is proportional to their ionic concentration. The authors conclude that the process is one of hydrolysis. The fact that secretin will stand boiling shows that it is neither a coagulable proteid nor a ferment. It is not precipitated by tannic acid, thus excluding bodies of alkaloid nature as well as di-amido compounds. This evidence points to secretion as being a body of relatively small molecular weight and not a colloid. It may be compared to adrenalin. The bodies of higher molecular weight, such as the toxins, which owe their activity, according to Ehrlich, to the fact that they can be directly assimilated by the cells of the body, and built up into the protoplasmic molecule, always give rise to the production of anti-bodies, a process which, while not preventing necessarily their utilization in the body, would prevent their acting as a physiological stimulus to certain definite cells. Adrenalin and secretin, on the other hand, belong to the substances which act by their physico-chemical properties, and whose physiological effect is determined by the total configuration of their molecule. That the pancreatic juice is not an anti-body to secretin is shown by the fact that both substances can be mixed without impairing the efficiency of the pancreatic juice. Secretin is easily oxidized by the body and is got rid of in this way. It also resembles adrenalin in not being specific for the individual or species. The evolution of this mechanism is therefore to be sought at some time anterior to the development of the vertebrates. Secretin increases likewise the secretion of bile. It has moreover no specific influence on any one constituent of the pancreatic juice. Secretin causes the pancreatic cells to turn out the whole of their granules, which they have accumulated during the resting stage. But secretin also excites a building up of the protoplasm and a new formation of granules. It has been shown by Dall that after the discharge of the granules the cells undergo a further involution, and become transformed into cells undistinguishable from those known as the islets of Langerhans, and believes that the latter repre-

sent stages in the functional activity of the secreting cells of the gland. The conditions under which secretin is formed, determine a close adaptation of the pancreatic activity to the needs of the animal. The presence of an excessive amount of acid in the duodenum is prevented by the reflex pyloric mechanism. The pancreatic juice as secreted contains only a weak proteolytic ferment. But it contains also trypsinogen. As it enters the gut, it causes a profuse secretion of intestinal juice, which contains a ferment, enterokinase, which acts on the trypsinogen converting ti into the active ferment, trypsin. Another interesting adaptation of the pancreas is that which results in the change of diet. Thus Weinland has shown that while the pancreatic juice of dogs normally does not contain lactase, yet when the animals are fed on milk (containing lastose), the ferment lactase is secreted. This reaction is absolutely specific. Although lactase is normally present in the intestinal mucous membrane, the appearance of this ferment in the pancreas is not due to the increase of its formation in the mucous membrane and escape into the blood. Extracts of the mucous membrane of the intestine of milk-fed dogs, when injected into the blood of biscuit-fed dogs, causes in the latter the production of lactase. What substance it is which is produced in the mucous membrane, and when carried to the pancreas and there excites the formation of lactose, is not known. It is destroyed by boiling. The chemical adaptations above described are more complex than any others yet investigated, and show the intimate correlation in the chemical reactions of different parts of the body.

Chemistry of Anesthesia.—A valuable study of certain physical and chemical properties of solutions of chloroform in water, saline, serum and hemoglobin was made by B. Moore and H. E. Roaf (*Proc. Royal Soc.*, May 28, 1904). The authors set out with the supposition that the anesthetic power of the hundreds of anesthetics is dependent upon some general type of interaction between the anesthetic and the active part of the cell. As the result of their experiments they draw the conclusion that chloroform forms an unstable chemical compound or physical aggregation with the proteids experimented with, and that it is carried in the blood in such a state of combination. Anesthesia is due to the formation of compounds of chloroform and other anesthetics with proteids which compounds limit the chemical activities of the protoplasm. The compounds are unstable, and remain formed only so long as the pressure of the anesthetic in the solution is maintained. Such compounds are formed not only by hemoglobin but also by serum proteid, and hence the position taken by the anesthetic in hemoglobin is not that of respiratory oxygen. This is further shown by the fact that the oxygen-carrying power of hemoglobin is not interfered with in the presence of chloroform. The facts upon which the authors rely as proofs of the formation of the above compounds in aggregates, are as follows: Chloroform has a much higher solubility in serum or hemoglobin solutions than in saline or water. Even in dilute solutions at the same pressure the amount of chloroform dissolved in serum or hemoglobin solution is considerably higher than in saline or water. The curve of pressures and concentrations in the case of water and saline is a straight line, while in the case of serum and hemoglobin solution it is a curve, showing association at the higher pressures. In the case of serum, chloroform causes a marked opalascence, and also a slow precipitation at room temperature, and at body temperature a rapid, though incomplete precipitation. In the case of hemoglobin, one and a half to two per cent. of chloroform causes a change of color and commencing precipitation at room temperature, which becomes almost complete in the uttermost at 40° C., while five per cent. and over causes complete precipitation at 0° C. The relations between chloroform pressure and concentration in solution have been worked out throughout a long range, from below the anesthetizing values (8 to 10 mm.) to nearly saturation in the case of water, saline, and serum. Attention is drawn to the important physical fact that with the same percentage of chloroform in the air breathed, serum or hemoglobin, and therefore the blood will take up much more chloroform than would water or saline under equal conditions. Thus at the anesthetizing pressures, and at 40° C., the coefficient of distribution in the case of water and saline is approximately 7.3; at room temperature (15° C.), these coefficients become 8.8 and 17.3 respectively.

HISTOLOGY, PATHOLOGY AND BACTERIOLOGY.

New Theory of Cancer.—It is not so long ago that a foremost scientist expressed himself doubtful as to whether the secret of the cancer-cell would ever be solved; it is therefore encouraging to encounter a new plausible theory, based upon accurate observation. In brief, G. Kelling (*Münch. med. Woch.*, June 14, 1904) believes with the older authors that the cancer cell is an embryonal cell endowed with all the energy of growth of young tissue; his theory differs, however, in that he does not regard it as a modified normal cell, but as altogether foreign and introduced from without. Thus embryonal cells are often ingested in raw eggs and the larvae of certain fish form a staple article of food. It is even possible that insects may inoculate these cells directly into the blood. Numerous experiments bear out this view, and the author was able to produce malignant neoplasms (malignant adenoma, carcinoma and sarcoma) in every case where comminuted embryonal tissue was injected into the veins of dogs. Still more convincing proof was obtained by the precipitation test. Several pyloric cancers, removed at operation, were communicated and injected into rabbits in increasing doses. The serum of these animals precipitated the extract of the cancer employed, human albumen and chicken albumen, but not albumen from any other source; thus making it exceedingly probable that the cancer cells took their origin from the embryonal tissue of ingested eggs. In support of the heterologous origin is the fact that nobody has ever observed the transition of normal into malignant epithelium even in the most early growths. It is a well-known fact in biology that all cells of one species possess the same number of nuclear chromosomes; cancer cells differ, however, in this respect from the other cells of the body. Furthermore, the cells behave differently toward X and radium rays and possess a different osmotic pressure, and there can hardly be any doubt that they are foreign.

Neutrophile Leucocytes in Infectious Diseases.—In certain febrile disorders, the leucocytes are within normal limits and chiefly polynuclear. According to J. Arneth (*Münch. med. Woch.*, June 21, 1904), it is a great mistake to pronounce such blood normal for the shape and structure of the nuclei possesses pronounced characteristics. In normal blood, the great majority of the nuclei of the neutrophiles possess two or three distinct lobes (isocytosis), but in all infections or intoxications, no matter whether a leucocytosis is present, cells with a single nucleus (myclocytes), an indented nucleus or a nucleus with only one lobe are more numerous (anisocytosis). Since these cells are the younger elements, their presence is probably an expression of increased disintegration of leucocytes.

Action of Roentgen Rays.—Most observers believe that the skin is affected primarily and most strongly by the X-rays if a portion of the body is exposed to

their influence, but G. Baermann and P. Linser (*Münch. med. Woch.*, June 7, 1904), make the startling statement that the blood vessels react before the skin. All lesions of the skin and connective tissue are thus an expression of nutritive disturbance secondary to vascular alteration. The following experiments support this view: If a diseased area of the skin is excised the raw surface may be covered with skin-graft which will rapidly heal in place. If the skin is first exposed to the Roentgen rays before it is transplanted the healing will be just as rapid, while an equal amount of exposure where the skin is not removed, will lead to superficial ulceration. One may even preserve the exposed grafts for two days in normal salt solution and then transplant them successfully on some other individual, showing that there is not the slightest loss of vitality. If a granulating surface is exposed and then covered with normal grafts, these will be cast off a few days later. The cornea of a rabbit will not be influenced by an exposure which causes falling out of the hair in other parts of the body, simply because the cornea contains no blood-vessels. The blood itself does not seem to be affected by the X-rays for even prolonged exposure, both in vivo and in vitro, did not change the microscopical appearance or the hemolytic power. The most important systemic reaction after exposure is a slight increase in temperature and an increased metabolism, manifesting itself in an abundance of nitrogeneous material in the urine.

The Circulatory System in Relation to the Curability of Tumors.—That tumors are more readily subjected to injury from without than normal tissues, because the circulating blood does not enter into close physiological relation with them, is the statement made by H. Ribbert (*Deutsche med. Woch.*, May 26, 1904). For tumors are not, like the regular organs, supplied by normally constructed vessels. The latter are simply tubes, made up in great part of endothelium, and not able to take part in blood pressure changes. Instead of branching like normal vessels, they constitute a network of interlacing canals. The size of these vessels, as regards their total area, is entirely out of proportion to the amount of tumor tissue supplied by them, for a large pedunculated growth may be nourished by a comparatively small vessel. The blood current is also slowed by the numerous sacculations and dilatations found in the course of these vessels. The rapid increase in size of certain tumors may be explained by assuming that the nutrient materials from the blood are entirely taken up by the tumor cells for purposes of growth and reproduction, as there are no other functionating powers to be supplied.

Leishmania-Donovani in the Soudan.—This disease is rare in Africa, unless it is that the cases have not been recognized. One reported by Sheffield Neave (*Brit. Med. Jour.*, May 28, 1904), being the second one discovered in that continent. The case was that of a boy, eight years of age, who had come from a village, 800 miles up the river, to be treated for chronic diarrhea. He recovered from this, but had a daily intermittant rise of temperature. He was extremely emaciated, his spleen reaching to the navel. All the important lymphatic glands were also enlarged. The peripheral blood was negative, but the splenic blood was crowded with Leishman-Donovan bodies. There was an enormous increase in the large mononuclears. Their count averaged 67 per cent. The history of the child was that the spleen had begun to enlarge in infancy. The cerebrospinal fluid was sterile and the urine contained nothing abnormal. The bodies have a somewhat oval form resembling a grain of wheat. They contained besides the nucleus a small rod-like body. This apparently varies in size, its greatest length being somewhere about half the diameter of an average red corpuscle. The bodies may occur singly, or they may appear to be collected in a spherical envelope about the size of a large white corpuscle. In this form or stage the individuals are often of differing sizes, and very often open spaces appear which suggest the thought that some have dropped out. If the slightest amount of water be mixed with the blood, or even if it be received into the citrate solution to prevent coagulation, the body will appear to disintegrate. This would seem to show that the next step in their life's history was not extracorporeal and that they do not escape by the urine.

Symmetrical Exotoses of the Scaphoid.—These symmetrical growths most frequently occur at the juncture of the epiphyses with the diaphyses of the long bones or upon the short bones which have multiple points of ossification. Fere and Deniker (*Revue de Chir.*, April, 1904), present the photographs and radiographs of a most interesting case in which this peculiar formation on the scaphoid was particularly well marked. It was so large as to be very prominent beneath the skin, and its base was about three centimeters in diameter. The only possible explanation of this phenomena is to be found in some anomaly occurring in the evolution of the individual.

The Leishman-Donovan Bodies.—These interesting parasites are often associated with splenomegaly in India and other tropical countries. They have usually been found in the spleen, liver and bone marrow. Sir Patrick Manson and George C. Low (*Brit. Med. Jour.*, May 28, 1904), report having found the bodies in the lymphatic glands of the mesentery in a patient dead from the disease. Sections of the pancreas, kidney and large and small intestines showed nothing. This information is valuable, because it is along these lines that the life history of the organism will have to be worked out.

Chemical Examination of Diseased Kidneys.—It is a peculiar fact, emphasized especially by A. Orgler (*Virchow's Archiv.*, Vol. 176, No. 3) that the chemical examination and microscopical appearance of pathological kidneys does not always correspond. Thus the microscope may give evidences of advanced fatty degeneration, while less fat will be found chemically than in normal organs. The author believes that many of the highly refractive granules that are looked upon as fat are not really fat, but protagon, a proteid, which also reduces osmic acid to some extent. Normally this protagon is contained in the cell in chemical combination with another proteid, which is destroyed by autolysis so that the protagon crystallizes out.

Pathology of the Aortic Valves.—Normally the asortic valves consist of three layers: A ventricular layer consisting chiefly of elastic fibers, a middle layer made up of loose connective tissue and an aortic layer of transverse fibers without elastic elements. Vessels do not occur in any layer. In the simplest pathological lesion, the slight thickening of the attached border, J. G. Mönckeberg (*Virchow's Archiv.*, Vol. 176, No. 3) could only detect a thickening of the fibrous inner layer with fatty degeneration of the intercellular substance and areas of necrosis and calcification. If more advanced, the process still remains restricted to the inner layer, where the necrotic foci become confluent and the deposit of lime is more marked. In far advanced cases with rigid, insufficient valves, the middle and outer layers are also implicated, and the process extends from its starting point, the base, to the free edge, so that the entire valve will become converted into

a rigid, unyielding plate. Where atheromatosis is secondary to a similar process in the beginning of the aorta the lesions are somewhat different, since the sclerosis begins in the outer layer and descends from the free to the attached border.

Pathology of Molluscum Contagiosum.—Many theories have been advanced to explain the contagious nature of that peculiar skin disease known as molluscum contagiosum, and various authors claim to have discovered protozoa within the cells of the tumors. H. Herzog (*Virchow's Archiv.*, Vol. 176, No. 3) finds, however, that these peculiar structures are solely due to hyaline degeneration and by a special stain he could accurately study the evolution of the so-called molluscum bodies from the normal basal epithelium. An interesting discovery which may explain the infectious nature of the disease, is the finding of large numbers of staphylocci in the excretary ducts and the surrounding tissues.

Action of Fluorescent Substances on Bacteria.—Bacteria seem to be more resistant to the action of photodynamic substances than protozoa. A. Jodlbauer and H. V. Tappeiner (*Münch. med. Woch.*, June 21, 1904), find that losin mixed with bacteria and exposed to the light has hardly any influence, erythrosin will kill off the culture in two to four days and rose bengale and methylene blue in one to two days. Certain other dyes are entirely inactive, though strongly poisonous to paramecium. This is explained best by a lack of diffusibility, the dye being unable to enter the protoplasm of the bacteria. Fluorescent substances produced by bacteria themselves are equally as toxic for bacteria as the synthetic dyes.

The Significance of the Zoological Distribution, the Nature of the Mitoses, and the Transmissibility of Cancer.—In a paper read before the Royal Society, E. F. Bashford and J. A. Murray (*Proc. of the Royal Society*, Vol. LXXIII, No. 489), give some interesting results of work done under the auspices of the Cancer Research Fund. As regards zoölogical distribution, it is found that cancer is found among all domesticated animals and many other vertebrates, even among animals living in a state of nature, e.g., wild mouse, codfish, gurnard. The clinical, pathological, anatomical and microscopical characters of these new growths are identical with those found in man in all essential features, although, the animals themselves are remotely related. The marked difference in the various environmental conditions, such as food, climate and mode of life, in the different forms in which malignant growths occur, shows that external conditions play at least a minor rôle in the etiology of cancer, that the cause of this disease is rather to be sought in the living cells. In general, malignant growths are found to occur chiefly in animals that are examined with care, as the horse, dog and cow, and are unrecorded in forms which are difficult to examine or do not reach old age in considerable numbers. The authors were able to confirm the important observations of Farmer, Moore and Walker, namely, that while the growing margin of carcinomata and sarcomata presented mitoses similar to those found in other tissues in repair and inflammation, certain cells in the deeper layers, after a slight increase in size, entered on mitosis with ring chromosomes similar to those found in the heterotype division of sporemother cells of plants and spermatocytes of animals, and like these, with chromosomes in number only half that characteristic of the mitoses of somatic cells. The latter investigators concluded that malignant new-growths are virtually reproductive tissue arising in abnormal situations and possessed of an independence and power of growth like that of the testis in the mammalian body. The authors confirmed the observations of Farmer, Moore and Walker, by studies on tumors from the trout, mouse and dog. They also noted the following important points: A complicated sequence of cell changes has been found to be characteristic of carcinoma and sarcoma alike. This sequence is the same as that which initiates the origin of the sexual generation in plants from the asexual, and is terminal in the history of the sexual cells in animals. All the cells of the malignant new growths do not undergo the reducing division, a certain number differentiate in the direction of the tissue among which they have arisen, and in secondary growths, when present, somatic mitoses occur in the growing margin, which is also a feature of the growth of cancer when transferred to a new host. The transmission of cancer from man to animals, or from one animal to another of different species, has never been successfully performed. But the authors confirmed the observations of Jensen, that it is possible to transplant cancer from one animal to another of the same species. The experiments were performed on mice. The new tumors that develop at the site of inoculation arise from the actual cells introduced. While many of these degenerate, a few remain by normal size, and these gradually increase in number. Transplantation is in fact identical with the process of metastasis as it occurs in the individual providing the tumor. The process is in no sense an infection, the tissues of the new host not participating in the formation of the new parenchyma. In every mouse in which the transplantation succeeds, the new growth may attain a weight equal to that of the animal itself, and over 400 such transplantations have been effected by Jensen in Copenhagen and the Cancer Research Fund in London. A mass of tumor, 16 pounds in weight, has thus actually arisen from the original one, and that without participation of the cells of the various hosts and without manifest change in structure. This power of growth is a phenomenon unparalleled in the mammalia. The authors emphasize the importance of distinguishing between the problem of the genesis of a malignant new growth, and that of the conditions which permit of its continued existence. Among 1,000 tame mice they found two with cancer. The wide zoölogical distribution of malignant new growths indicates that the cause of cancer is to be sought in a disturbance of those phenomena of reproduction and cell-life which are common to the forms in which it occurs. The authors' observations also showed that malignant new growths are always local in origin and of themselves produce no evident constitutional disturbances whatever. The evidence which they have advanced that cancer is an irregular and localized manifestation of a process, otherwise natural to the life-cycle of all organisms, probably explains why it is that malignant new-growths and their extensive secondary products, are devoid of a specific symptomatology.

The Liver in Portal Thrombosis.—According to F. Steinhaus (*Deut. Arch. f. klin. Med.*, Vol. 80, Nos. 3 and 4) thrombosis of the portal vein may occur both with and without distinct disease of the walls of the vein. In the majority of cases no changes take place in the liver, since the circulation of blood is not impeded and the liver receives its full amount of nutrition. If, however, the venous circulation is interfered with, especially the hepatic venous circulation with diminished arterial blood supply, the so-called atrophic red infarcts will result. These foci are sharply circumscribed, rectangular or wedge-shaped and generally dark-red in color. Microscopically, the capillaries are

distended with blood, the liver cells are atrophic and the portal branches thrombosed. If the thrombosis extends into the interlobular branches of the portal vein, necrosis and hemorrhage will follow. The branches of the hepatic artery may be normal or diseased, yet the arterial blood supply is completely shut off here. Acute thrombosis manifests itself clinically in severe abdominal pain and copious hemorrhages from those organs drained by the portal vein. Complete occlusion is generally fatal, partial obstruction will eventually lead to ascites, splenic tumor and periodic hemorrhage. The most common etiology is syphilis, tuberculous peritonitis, compression by tumors, glands and gall-stones.

Chronic Infection and Subinfection by the Colon Bacillus.—By repeated intravenous injections of living cultures of the colon bacillus into rabbits, G. A. Charlton (*Jour. of Med. Research*, May, 1904), caused the development of a state of advanced anemia, not quite comparable with any of the classic forms seen in man. In some respects it resembles pernicious anemia, namely, in the very great diminution of erythrocytes, the marked poikilocytosis, and the appearance of nucleated red corpuscles. On the other hand, it differs from pernicious anemia in the fall of the amount of hemoglobin being parallel with the decrease of the red corpuscles, in the absence of a distinct and extensive Inincke's siderosis, in the absence of any clear evidence of inflammatory or other disturbances of the digestive tract, and of well marked changes in the bone-marrow. In the advanced stage of this anemia a diffuse degeneration of the spinal cord was set up, affecting the posterior and lateral columns of the cord, in the lumbar and dorsal regions. This degeneration consisted in a fatty degeneration of the myelin sheaths of the fibers and certain pigmentary changes, in the nerve-cell bodies of the gray matter. The ventral columns of the cord and the gray matter were not affected. Similar conditions of anemia and spinal cord degeneration could not be produced by injecting killed cultures of the colon bacillus, nor by filtered cultures. When the living cultures were acted upon by pepsin, and injected intravenously, they did not differ materially in their action from the original living cultures.

Lymphatic Glands in Sleeping Sickness.—In examining the contents of the lymphatic glands during life in patients suffering from sleeping sickness, E. D. W. Greig and A. C. H. Gray (*Proc. Royal Soc.*, June 22, 1904) found the presence of actively motile trypanosomes. The latter are far more numerous in the glands than in the blood or cerebro-spinal fluid, and the examination of fluid removed from the glands will prove to be a much more rapid and satisfactory method of diagnosing early cases of the disease. The authors believe that these observations throw a new light upon the glandular enlargements which have been so constantly noticed in sleeping sickness, and that the disease is essentially a polyadenitis brought about by the arrest of the trypanosomes in the glands where many of them are destroyed, but whence some escape from time to time into the blood stream and this occasions the increase which has been observed in the peripheral circulation.

Heat Regulation and Death Temperatures.—In studying the variations of the bodily temperature as death approaches E. M. Corner and J. E. Sawyer (*Proc. Royal Soc.*, May 28, 1904) propose the following theory for the causation of pyrexia. It is due to two factors, to an augmented production of heat owing to the activity of the thermogenetic centers in the spinal cord being no longer perfectly controlled by the higher center in the brain, and to a diminished loss of heat owing to the weakening of the functions of the thermolytic center; the power of the two higher centers being weakened or paralyzed by the morbid products or toxins of the affection from which the organism is suffering. In other words, normal temperature is preserved by a mutual see-saw action of these centers.

Lipase in the Urine in Experimental Pancreatic Disease.—It is possible to show the presence of lipase in the urine and to roughly estimate the amount, according to A. W. Hewlett (*Jour. of Med. Research*, May, 1904). Very little, if any, lipase is present in normal urine. Lipase appears in the urine after a variety of insults to the pancreas of dogs. It was found in great amount as a result of experimental acute hemorrhagic pancreatitis. It was also found over a period of from three to five days after obstruction of the pancreatic duct. It is probable that severe pancreatic trauma may cause the appearance of lipase in the urine. The above are the conditions in which fat necroses are most apt to occur in human pancreatic disease.

The Action of Radium on Micro-Organisms.—A specimen of pure radium bromide was used in a series of experiments by A. B. Green. (*Proc. Royal Soc.*, May 28, 1903) in an effort to determine the germicidal powers of the emanations, and whether the radio-activity may be imparted to bacteria. In using calf vaccine with its contained extraneous bacteria, the *S. pyogenes aureus, S. pyogenes albus, S. cereus flavus, S. cereus albus*, the author found that the specific germ in no case survived a longer exposure to radium than 22 hours, at the end of which time it had completely lost its ability to cause vesiculation or any visible irritation at the site of inoculation on a calf. The extraneous bacteria did not survive after 15 hours. The following species of micro-organisms were separately tested: the extraneous germs above mentioned, and *S. pyogenes, B. prodigiosus, B. proteus vulgaris, B. pyocyaneus, B. typhosus, B. coli communis, B. Mallei, B. pestis, B. tuberculosis*, the B. of Malta fever, *Spirillum cholerae Asiaticae*, and the sporing cultures of *B. mesentericus vulgatus, B. mesentericus ruber, B. subtilis, B. anthracis, B. tetani*, Gärtner's B., the bacillus of malignant edema, and the bacillus of Rauschbrand. All the non-sporebearing bacteria mentioned were killed after exposure to radium for 2-14 hours. The bacteria containing spores were by far the most resistant to the germicidal action of radium, for they were not killed by less than 72 hours' exposure. It has been found that after exposure at a distance of one min. to the radium emanations for 24 to 120 hours, micro-organisms may themselves show signs of radio-activity. It has not yet been determined whether living micro-organisms can exhibit induced radio-activity. No radio-activity has been found in bacteria not exposed to the action of radium.

The Rôle of the Blood Fluids in Connection with Phagocytosis.—A continuation of their interesting researches along this line has been made by A. E. Wright and S. R. Douglas (*Proc. Royal Soc.*, March 7, 1904). In their previous experiments the authors found that the phagocytosis which occurs when cultures of *S. pyogenes* are added to the human blood is directly dependent upon the presence of certain substances in the blood which exert a specific effect upon the bacteria. The bacteriotropic substances thus revealed were denoted by the term "apsonius." The authors now find that the apsonic power is exerted not exclusively upon the *Staphylococcus pyogenes*, but also upon the *B. pestis*, the *Micrococcus melitensis*, the *Diplococcus pneumoniae* of Fraenkel, the *B. coli*, the *B. dysenteriae* (Shiga), the *B. anthracis*, the *B. typhosus* and the *Vibrio cholerae*

Asiaticæ. As far as the authors have gone, the *B. xerosis* have proved to be the only pathogenetic bacteria which are insensible to this action of the blood fluids. The bacteria are accordingly classified as follows: (1) Bacteria which are eminently sensible to the bactericidal, bacteriolytic, and apsonic action of the normal human blood fluids.—The *B. typhosus* and the *Vibrio choleræ Asiaticæ*. (2) Bacteria which are in some measure sensible to the bactericidal action of the normal human blood fluids, but are eminently sensible to its apsonic action.—The *B. coli* and the *B. dysenteriæ*. (3) Bacteria which are absolutely insensible to the bactericidal action of the normal human blood fluids, but are eminently sensible to the apsonic action of these fluids. The *Staphylococcus pyogenes*, the *B. pestis*, the *Micrococcus melitensis*, the *Diplococcus pneumoniæ*. (4) Bacteria which are insensible both to the bactericidal and to the apsonic action of human blood fluids.—The *B. diphtheriæ* and the *B. xerosis*. It has been shown that patients who are the subjects of acne, sycosis, or boils are characterized by defective phagocytic power for the *Staphylococcus pyogenes*. The latter is dependent upon a defect of apsonic power. The authors demonstrated that successful immunization against *Staphylococcus pyogenes* is dependent upon the elaboration of apsonius in the system of the inoculated patient, and suggest that successful immunization against plague and Malta fever and against streptococcal invasions may be likewise dependent upon the elaboration of apsonius.

The Influence of Alcohol, Ether, and Chloroform on Natural Immunity.—That alcohol, ether, and chloroform have a decidedly detrimental influence in the natural defenses against infection has been proved experimentally by G. RUBIN (*Jour. of Infectious Diseases*, May 30, 1904), who also found that this lowering or suspension of the resisting power of the animal is not due to any apparent organic lesions. The narcotics appear to affect directly the substance or substances which inhibit the growth and toxic action of bacteria in the normal animal and these substances are either the leucocytes themselves or something derived from them, or both. Snee has shown in his work that alcohol and ether suspend also conferred immunity against a specific microbe. The period of detrimental action of the narcotic depends largely on the amount administered, the depth of narcosis, and the rapidity of its elimination from the system. Some of the narcotized animals that were employed in other experiments with infectious material 24 hours after narcotization fared as well as the new rabbits.

OBSTETRICS AND GYNECOLOGY.

Eclampsia.—An excellent review of our present knowledge of this subject is presented by P. ZWEIFEL (*Archiv. f. Gyn.*, Vol. 72), in which particular attention is paid to the quantitative chemical analyses of the urine and blood. The former have been directed to the estimation in the urine of the albumin, and nitrogenous or non-nitrogenous disintegration products of albumin, and the latter to the quantitative analysis of the blood as regards uric acid and the salts of ammonia. At the beginning of an eclampsia, the urine contains a diminished amount of uric acid, which is the end product of albumin metabolism, and which increases again as recovery is brought about. There is no increase to be found, however, of the amount of uric acid in the blood, nor is there any increase of the NH_3. The conclusion to be drawn from these facts is that there is a marked interference in the process of oxydation of the albumin. The author is inclined to the belief that lactic acid or neutral sulphur is the toxic product which induces the convulsions. In the section on treatment, Zweifel advises as a prophylactic measure, the administration of tartrates in the food, which should comprise plenty of fruit and vegetables and little meat or eggs. Farinaceous foods and sugar may be taken in moderation, as they are not concerned in this disturbed metabolism. When the attacks have already come on he advises the administration of tartrate of potash or soda, if necessary through the stomach tube, and also the subcutaneous transfusion of a solution containing bicarbonate of soda (0.5 per cent.) and sodium chloride (0.5 per cent.) in distilled water. Narcosis by chloroform or other drugs is not recommended, and diaphoresis has not been followed in his experience, by sufficiently favorable results to warrant its employment. Immediate delivery is considered by Zweifel to be the most effective measure for saving the life of the patient, and he recommends forcible dilatation of the cervix when necessary, by means of bags in preference to instruments of the Bossi type. If this is ineffectual, he makes deep incisions into the cervix, essentially a vaginal Cæsarian section. The first indication in all cases, however, when they first come to the attention of the physician during the attack, is to immediately rupture the members.

Laryngeal Tuberculosis and Pregnancy.—The association between these two conditions has been considered intimate enough to warrant the induction of labor where tuberculosis of the larynx was present. R. SOKOLOWSKY (*Berl. klin. Woch.*, 1904, No. 27) reports two cases where even this radical precedure failed in its effects and the disease progressed until the patients died within a few weeks after delivery. In one woman labor was induced during the eighth month, in the other during the sixth. In connection with two similar cases lately reported from another source, the author believes that the interruption of pregnancy is of no value unless done during the early months and woman afflicted with tuberculous laryngitis should be warned of their danger and a facultative sterility advised, in order that they may not become exposed to these grave possibilities.

Prognosis and Treatment of Puerperal Pyemia.—As the results of his extensive experiences, E. OPITZ (*Deut. klin. Woch.*, 1904, No. 27) believes that only in exceptional instances should operative treatment be directed toward ligation or removal of the diseased veins, as recommended by Trendelenburg, or toward total extirpation of the uterus as suggested by Schultze. The indications and the recognition of the side on which the process is localized, are entirely too difficult and uncertain. The objects of treatment should be to strengthen the system in its fight against the infection and to avoid further damage. The author's recommendations are, proper nourishment (albuminoids, sugar, milk, little alcohol); an abundance of fluid by os, rectum and infusions; absolute rest; sedatives, such as pyramidon, phenacetin, salipyrin, sometimes camphor or digitalis. Diarrhea he does not combat. No favorable results followed the injection of turpentine oil or silver salts. In the future he believes that good results may be looked for with treatment by nuclein, antipyrin and collargol (intravenously). Good and efficient nursing is of the greatest importance.

Borax in the Treatment of Epilepsy.—This much lauded remedy has been given a practical trial by J. HOPPE (*Berl. klin. Woch.*, 1904, No. 27) in a series of 12 cases. In seven of these the drug was followed by no favorable effect whatever, and in some few instances the patients grew worse. The latter presented some functional derangements of the excretory organs.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the MEDICAL NEWS will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

SATURDAY, AUGUST 6, 1904.

"THE WAY WE HAVE IN THE ARMY."

THE qualifications necessary for admission into the Medical Corps of the United States Army have been again increased and the standard raised. These amended regulations took effect on July 1, 1904, and will, without doubt, not only increase the efficacy of the Service, but improve it materially in other ways. The immediate appointment of applicants for commissions, after successful physical and professional examinations, the latter embracing all subjects of medical education, has been discontinued. Hereafter all candidates will be subjected to a preliminary examination, and then, if successful, to a final or qualifying one, with a course of instruction at the Army Medical School at Washington intervening.

The preliminary examination now consists of a rigid inquiry into the physical qualifications of those seeking commissions. This, if successfully passed, is followed by a written examination in the following subjects: Mathematics (arithmetic, algebra, plane geometry), geography, history (especially of the United States), Latin grammar and the reading of easy Latin prose; English grammar, orthography and composition, anatomy, physiology, therapeutics and normal histology. The subjects in general education, the circular states, are "an essential part of the examination and cannot under any circumstances be waived."

These preliminary examinations are conducted concurrently throughout the United States by bands of medical officers at convenient points. The questions submitted to all aspirants will be the same, thus insuring a thoroughly competitive and fair test, and all papers will be graded and criticized at the War Department, in Washington. Applicants who attain a general average of 80 per cent. will be employed as contract surgeons and ordered to the Army Medical School for instruction as candidates to the Medical Corps of the Army. If, however, the number of those successfully attaining the required average is in excess of the accommodations at the school, the requisite number will be selected according to their relative standing in the examination.

The course of instruction at the Army Medical School will, the authorities state, consist of lectures and practical work in subjects peculiarly appropriate to the duties which a medical officer is called upon to perform. While at this school the students will be held under military discipline and character and general deportment closely observed. All this is a step in the right direction, and nothing more seems possible unless indeed to require that all candidates must be college graduates, which will undoubtedly be eventually the case. Meanwhile the changes will unquestionably raise the status of the medical corps and strengthen the conjunction between "an officer and a gentleman" and render the terms synonymous. But we do not believe that this legislative action will play the part of the Guatamalian ants to the boll weevils, or that it will kill the microbe that lies at the roots of the trouble between the line and the staff, viz., the craving on the part of the latter for military titles and distinctions to which it has no moral right, either by tradition or association. For, while there is nothing in the training of the curriculum at West Point to prevent a graduate from becoming an excellent commissary officer, or a first-class paymaster, yet there is also nothing that could render him capable of assuming the duties of a surgeon, and the professions are as absolutely distinct in the Service as they are in civil life.

Now, the profession of medicine is an honorable estate. It certainly takes as many years of hard study, the possession of as much, if not more, intellect to become a good doctor as it does to become a good soldier, and the one profession

undoubtedly stands as high in the estimation of the community as the other. Why, then, should the representatives of the one desire to assume the appellations and designations of the other? That they do so desire is unquestionably the rule, and it is unfortunately one of those proverbially poor rules that does not work both ways. For, while the army surgeon, particularly of late years, is most insistent of his rank and most tenacious of any military designation that it may represent, such as captain and major, the case is yet to be reported where even a second lieutenant sought to infer that he belonged to the medical staff of the Army.

And this is the humiliating part of it to the general medical profession at large. That these men who have the brains and the assiduity to pass these examinations should by their claim to titles that belong exclusively by habit and tradition to another branch of the Service with which they have no connection, and tacitly admit that even if they are not absolutely ashamed of their profession, yet they *do* consider it inferior to that of their purely military associates. Surely peace has its victories as well as war, and in the future if young men are emulous of the laurel wreaths of the firing line and discontented with the bay leaves of the hospital tent, they had better enter the Academy at West Point in the beginning. Then they will become real "sure enough" generals and colonels and not majors and captains in the Medical Corps.

Some few years since there was a doctor who had been put on the retired list of the Army. He was an old surgeon and a good one, too; so good that besides his retired pay he had been rewarded by a grateful government with high honors and "a ribbon to pin on his breast" as a pledge to assure him thereof. Soon after that a modest sign appeared at his door bearing his name with the conventional M.D. of the ordinary physician's plate. Then he settled in a quiet little Canadian watering place for the summers and became a part of it.

Meeting by chance a physician who enjoys one of the largest practices in one of our Western cities, at the hotel, he entered into conversation with him and chatted some little time on medical topics. The next morning the physician happened to be on the front steps as the surgeon passed the hotel. Down the walk he came, head erect, shoulders squared and chest protruding, his neck confined in a starched stock and his feet firmly planted in cadence with the illusive strains of an imaginary brass band. As he swept by he brought his cane to a marching salute, which was at once returned by the cheery "Good morning, Doctor," of the unconscious physician. The column of one instantly halted, faced to the right and in the first position of the soldier, with his little finger held lovingly in the rear of the seam of the pantaloons, he thundered out, "*Not* Doctor, Sir; Colonel, Colonel, Colonel!"

The physician was thunderstruck, but he grasped the situation. He instantly apologized on the grounds of the likeness of the speaker to a doctor with whom he had conversed on the previous evening and alluded to the sign which he said "was indicative of seeking medical practice and which did not have any of the earmarks of a d—d recruiting officer." The surgeon admitted that the sign was his, and then the physician, with all the incisiveness born of Boston, which was enhanced rather than tempered by the acquired breeziness of the West, proceeded to inform him what he and the profession at large thought of "a Judas that put his hand into the dish of medical patronage and then denied his Master."

Could anything be more ridiculous, unless it is the fact that when a foreign, world-celebrated physician called on a man who had once been Chief of the Bureau of Medicine and Surgery in the Navy Department—his butler reprovingly said when asked "if the Doctor was at home," "No, sah, the Admiral is not receiving to-day." Luckily these things right themselves when they have been sufficiently laughed at and ridiculed, but the army surgeon should be content with his own profession, which he has long led, as compared with the armies of other countries, and not seek a military position, which at the best would only cause him to be classed with that charmingly alluring, but distinctly hybrid individual, one "Captain Jinks, of the Horse Marines."

"BUTTON BUTTON."

Robert F. Weir, speaking recently on the disadvantages of the Murphy button, said: "This remarkable ingenious contrivance has furthered the development of abdominal surgery more than any of the many hundred kindred devices which have been suggested. Without the courage which its facile employment and its generous assurance of success has given to surgeons, it would have taken many more years than have passed since its introduction to have accomplished what already has been done."

If this be true of the Murphy button, and the authority quoted stands among the highest in the world,—it must also, in a less degree, be true of the many minor and, in general, imitative instruments to which Dr. Weir referred. On the principle, however, that dogs have their day; irrespective entirely of the fact that fashion in surgery is quite as imperative as it is on the back of the fair sex (and entirely in accordance and in agreement with Dr. Weir's laudation of the Murphy button, has not the time come to inquire seriously into the question of its present position in the surgeon's arnamentarium?

That there is no fair answer to this save an affirmative one, is vouchsafed in part by the broad minded attitude of the distinguished inventor of this button,—Dr. John B. Murphy. At the recent meeting of the American Medical Association in Atlantic City, in reply to Dr. Weir's criticisms of the button, Dr. Murphy said that more had been expected of the invention, more burdens had been cast upon it than he himself had ever intended or desired. He very freely admitted that it was open to strenuous objection. He did not deny that occasionally after performing gastro-enterostomy, the button fell into the stomach, and he delighted the audience, and Dr. Weir as well, by saying that the only time this accident had befallen him, had been when he had made use of the well-known Weir modification of his button by which a flange was so fitted as supposedly to prevent this catastrophe.

Within the past ten years the definite decision has taken firm root that it is unsurgical in the truest sense of the word to introduce non-absorbable materials into the tissues. It may be said with truth that Murphy's button does not technically fall within the pale of this decision, and although academically perhaps, from the standpoint that the inside of the gut is upon the outside of the stomach, nevertheless, from a practical viewpoint and clinically, when a man gets a button in his belly, or has one lodged for good in his intestine, the button is inside of him so far as his comfort goes.

It is perhaps easier to forecast the future of such a contrivance as the button by watching the history of other non-absorbable devices. Eight years ago, a great many of the so-called Phelps' woven wire mattrass pads were introduced into the abdominal wall to repair its lack, in certain cases after the reduction of large herniæ. Although many of these pads froze, as it were, into place, through the kind agency of asepsis, they never, without exception, save perhaps the one which proves the rule, proved to be either remedial of the lesion or comfortable to the patient. By the usual process of nature, who has at length forced upon us the fact that she abhors foreign bodies as well as vacua, they were one and all forced to the surface and were driven out through a sore and sinned against skin. Does any one now employ these pads? Is not the use of silver wire as a bone-suturing material, even, going utterly and entirely out of use? The conclusion is now self-evident that the patient might just as well be expected to wear permanently the external splints used to coapt a bone, as to endure the existence of permanent internal splints in the shape of silver wire.

The prognosis then for the life of the Murphy button, based upon an examination of the fate of other non-absorbables, is distinctly bad.

What prognosis is furnished by that most sensitive of all indicators, the Zeitgeist? Everywhere far and near, there is an indication that surgeons are seeking after something better than the button. It might be said that that was simply an indication of an effort at progress, but the extent, and persistent earnestness and variety of the search, indicate something more than that. Many of these attempted improvements on the button are too well known to deserve citation, but there is one which was presented before the recent meeting of the American Surgical Association at St. Louis, which deserves more than passing interest. This is not because of the probability that it will definitely supersede the button, even in part, but because its very ingeniousness shows the need for some suitable contrivance or method.

Dr. F. B. Harrington, of Boston, has devised an aluminum bobbin, which is constructed out of four separate segments of a circle. Little shoulders abut and when held tightly in position by a catgut strand, the ring is completely rigid. A convenient handle coupled to the ring serves to hold it during the period of its insertion. This ring has given, in the hands of its distinguished inventor, admirable results. It breaks up into four segments weighing but a few grams, each one of which has four rather sharp corners. They have been observed under the X-ray to be carried by the motor power of the stomach from the artificial opening to and through the pylorus.

Are sixteen points of possible danger preferable to the well tried but by no means infallible Murphy button?

Before this question can be answered from the

experience of many hundreds of operators as the delicacy and ingeniousness of the contrivance justifies that it should be, it is to be hoped that a more felicitous means of accomplishing what these non-absorbable means do so well, will have been devised by an equally certain but more innocous absorbable material.

ECHOES AND NEWS.

NEW YORK.

Appointment of Dr. Norris.—At the meeting of the Board of Trustees, held on Wednesday, July 27, 1904, Dr. Charles Norris, of New York, was appointed Director of the Pathological Laboratories in the Department of Bellevue and Allied Hospitals, said appointment to date from October 1, 1904. Dr. Norris has been an active worker in pathology for a number of years. For the past two years he has been teaching in the Pathological Department of Columbia University. Bellevue and this city are fortunate in having obtained the services of so able a pathologist.

Appointment of Dr. Prentiss.—Dr. Henry Prentiss, instructor in practical anatomy in the Bellevue Medical College of this city, has been appointed Professor of Anatomy in the University of Iowa.

Rockefeller Institute Plans.—Plans have been filed for the new laboratory building to be erected on Exterior Street, east of Avenue A, for the Rockefeller Institute of Medical Research, of which Dr. William H. Welch, of Johns Hopkins University, is president, and Dr. S. Flexner, Resident Director. It is to be a five-story edifice, 136x60, with a façade of limestone and brick. It will be decorated with pilasters of brick, and have a porch entrance flanked with decorative columns for the support of electric lights. The first floor will be an assembly hall, with a library and study and directors' room. The upper floors will contain large general and special laboratories and research rooms. The fifth will have a dining hall and living quarters, and the roof a special operating room and quarters for the animals under examination. Adjoining the main building will be a two-story building for the animals used by the doctors, and powerhouse. The cost of the buildings is estimated at $325,000.

The National Association of Tuberculosis.—The National Association for the Study and Prevention of Tuberculosis, which was organized at Atlantic City on June 6, is to begin active work on Monday next. An office has been secured in the Associated Charities Building at Twenty-second Street and Fourth Avenue, and Mrs. Florence F. Colby has been elected assistant secretary to start the work. An executive secretary will be elected in September. The association promotors are starting out with the idea that at least $50,000 can be raised yearly to carry on its crusade, which is to be mainly one of education. There is no idea of founding any sanitarium, hospital or dispensary for the treatment of the disease. It is not likely that a laboratory even will be instituted at first, although that may be done later. The work planned for the first year at least is the collection and dissemination of information of every sort touching the disease. Statistics will be collected and pressed on the attention of municipal bodies and institutions in order to get them to make scientific warfare against the spread of the infection. The primary purpose is to make the association headquarters a clearing house for tuberculosis lore. The formation of local associations and committees will also be urged and assisted in every possible way. It is probable that a special journal devoted to tuberculosis will be published; but this point is not quite decided. One of the first definite enterprises will be the publication of a Tuberculosis Directory. This will be done in cooperation with the Charity Organization Society, whose tuberculosis statistician, Miss Lillian Brandt, has already in hand a great deal of the necessary information, including particulars of 125 hospitals and sanitaria in this country and Canada specially equipped for the treatment of tuberculosis. The crusade promises to be an active one, and all physicians in the country can greatly aid the National Society in its propaganda.

Reduction in Infant Mortality.—Thanks to the efforts of the summer corps of doctors and nurses, aided by more favorable weather, infant mortality decreased last week. From a total of 565 deaths the week before from diarrheal diseases, of which 523 were children under two years, the death list from the same causes in the week ended Saturday, July 30, dropped to 426, of which 388 were children under two years. With this decrease the death rate from all causes came down from 23.46 to 20.65, the lowest is seven weeks. When the deaths among the children became so appalling in number warnings were sent out and sanitary laws enforced with renewed vigilance by the city Health Department. The summer corps searched out mothers of babies, ill or well, in the tenements and preached the gospel of boiled water, pure milk, proper clothing, fresh air and all the precautions that make for health. The summer corps visited 5,130 houses, sheltering 26,963 families, last week, and treated 362 ill children. The corps distributed 8,636 circulars, giving directions to mothers of young babies, and gave out 580 milk tickets and examined 2,852 children for the St. John's Guild boats. Not a quarter of the guild tickets were used, however. The mothers retain their fear of excursion boats caused by the fate of the Slocum excursionists early in the summer, and even the enticing prospect of a free ride and the recommendation and assurance of the doctor are not sufficient to induce them to risk themselves and their children aboard. As showing that the tenement conditions are largely responsible for the high mortality of children the deaths from diarrheal diseases are confined almost wholly to Manhattan and Brooklyn, and to that part of each borough where the congestion is greatest and especially where the foreign element is most conspicuous.

PHILADELPHIA.

Beriberi in Port.—When the sugar-laden bark Foohng Suey arrived at the State quarantine station at Marcus Hook the past week it was found that eight cases of beriberi were on board. One sailor had died of the disease at sea. After the sick men were removed, the vessel was fumigated for twenty-four hours and then allowed to come to the city. Some criticism has been made regarding the action of the government physicians at Reedy Island, who passed the ship without subjecting it to fumigation.

Heads of Quarantined Houses Warned.—A circular issued by the Bureau of Health directs the heads of quarantined houses to see that all bottles or other vessels that have contained milk be disinfected by or under the supervision of the bureau before they are removed from the place. Milk dealers are also notified not to collect such bottles until properly prepared. This is to prevent the spread of contagious diseases from house to house.

State Examinations Unsatisfactory.—The President of the State Board of Medical Examiners is quoted

as saying that the results of the recent examination of 376 applicants for State license are highly unsatisfactory. Detailed report will not be made until after the meeting of the board on August 8, at which time some action may be taken to better existing conditions. The suggestion that the charters of certain medical institutions be revoked is not among the impossibilities.

New Pure Food Law Being Prepared.—Legislative acts being prepared for introduction will give the Department of Health of Philadelphia specific power to stop the sale of adulterated and preserved foods. At present this is impossible, and many dealers escape. State Commissioner Warren is in favor of imprisonment for men convicted a second time of adulterating foods, the first offense having been punished by a fine.

Smallpox and Vaccination.—Director Martin has issued a statement in which he declares that smallpox no longer exists in this city. Among other things, he says: "After a three years' struggle, the results of which have been extremely slow in appearing, the smallpox epidemic, which has cost Philadelphia thousands of lives and millions of dollars, has reached an end. It should never have occurred and could have been avoided with absolute certainty had the community, as a whole, been properly protected by vaccination. The responsibility of preventing a recurrent epidemic rests with the Health Department and the medical profession of Philadelphia." After asking for the vaccination of all persons not properly protected he states: "We consider as evidence of proper protection against smallpox in persons under twelve years of age the presence of at least one typical vaccination scar. In persons more than twelve years of age, the presence of at least two typical scars, made at different times, or the evidence of successful vaccination practised within five years."

CHICAGO.

Allegations of Cruelty Baseless.—After examining fifty employees of the Northern Hospital for the Insane, the State Board of Charities, represented by a majority of its members, voted that the charges of abuse and cruelty preferred by the Elgin Trades Council in its letter to Governor Yates were utterly baseless. The board is charged, however, with not giving the members of the Trades Council, who have made affidavit to special cases of cruelty, proper opportunity to appear. The board has what purported to be the original charges, and made an investigation among the employees of the asylum to discover if any attendant, nurse, physician, or other official, had committed any of the brutal deeds set forth in the accusing document, and each of the witnesses asserted there could be no possible premises upon which to build tales of inhumanity.

Work of Nurse Association.—The report of the Visiting Nurse Association for the month of July shows that 798 patients were attended and 3,679 visits made. The principal cases treated were consumption, typhoid fever, and children's diseases. The work of the Association is greatly hampered by lack of funds, more nurses being needed at once.

New Building for Cripples.—Mrs. R. H. McElwee, of Lake Forest (Illinois), has, in charity's cause, donated a new building to the Home for Destitute Crippled Children. The gift will be in the form of an extension to the present structure, and will cost from $30,000 to $40,000. The work of construction will soon begin. The institution as it stands affords accommodation for 35 or 40 crippled little ones, but even with that limited number its wards are overcrowded. The new wing will house 80 more and will be devoted largely to orthopedic cases.

The Murder Habit.—Statistics of murders which have just been compiled in Italy show that while in France the annual rate is one murder to every 100,000 inhabitants, in Northern Italy it is 4, in the middle provinces 24, and in the southern provinces, including Naples and Sicily, it is 30. Last year the Cook County (Illinois) Coroner held inquests in 118 cases of homicide, of which only 11 were reported by him as justifiable. This is at the rate of about 6 per every 100,000 of the population. Chicago can hardly take pride in the fact that her murder record is five times better than that of Naples and Sicily. On the contrary, she can feel nothing but shame that it is six times worse than that of France. Probably the local record for the current year will be better than that of last year, for the numerous instances of severe penalties inflicted by juries during the first six months of the year cannot fail to have their effect. Nevertheless, the need of improvement will still be marked, and improvement can come only as the community places a higher value on human life and insists that all public officials take the most vigorous methods to bring all murderers to justice.

Changes in Faculty.—Professors Orville E. Brown, Elias P. Lyon, and Chas. H. Neilson, of the Department of Physiology of the University of Chicago, have resigned to accept similar positions on the faculty of the University of St. Louis.

Will of Dr. N. S. Davis.—The will of the late Dr. N. S. Davis, father of the American Medical Association, disposes of an estate valued at $39,000, of which $25,000 is real estate. The homestead is bequeathed to his widow, his library to his son, and a perpetual scholarship in Northwestern University to his grandson, Frank H. Davis.

Opening of Tuberculosis Hospital.—The new hospital for the treatment of consumptives at Dunning was turned over to the officials recently, and a little later all the patients in the old building were transferred. The new hospital consists of five cottages, and will accommodate 160 patients. The old building is to be used as a hospital for the sick insane.

GENERAL.

Fate of the Substitutor in New Orleans.—Recent developments in New Orleans show that the owners of a certain company operating under the name of the German Chemical Company have been arrested and arraigned under charges of obtaining money under false pretenses by attempting to sell modern chemicals as pure when they were found to be gross adulterations. Phenacetin was found to be 65 per cent. acetaniled and 35 per cent. phenacetin, and other products treated in like manner. We might hope for more strict regulations in other parts of the country if the physician is to have any assurance of the real quality of his wares.

Koch's Successor.—Professor Gaffky, who was appointed the successor of Koch as director of the Institute for Infectious Diseases in Berlin at Professor Koch's desire, was associated with his predecessor in 1883-84 in the cholera expedition sent by the German Government to Egypt and India, and helped him prepare the report thereon. In 1888 he became professor of hygiene at the University of Giessen, and during the Hamburg cholera epidemic, four years later, he was engaged by that city as expert adviser. In 1897 he was at the head of the dangerous expedition sent to India by the Government to study the plague. Gaffky was born at Hanover, in 1850, and began his career as military surgeon in the Prussian army.

Liability for Medical Attention—"Dowieism."—The Supreme Court of Indiana recently affirmed the de-

cision on the "Christian Science case" in which the Clinton County court discharged Joseph Chenoweth from a prosecution for involuntary manslaughter, in allowing his baby to die of acute pneumonia without calling a physician. The baby was nine months old, and had whooping-cough. The disease finally became acute and Chenoweth called in an elder, who "annointed the child with oil and prayed for the healing thereof." He also communicated with one Dowie, at Chicago, and caused him to pray for the child. His neighbors urged that a physician be called in, but he refused to have a physician or to give the baby medicine, because he believed in "Divine healing," and offered and cited the "Word of God" as his justification for the refusal. Chenoweth was able to hire a physician had he desired one. The physicians who were called as witnesses against Chenoweth testified that so young a baby would probably have died if a physician had been called after bronchial pneumonia developed, but that its life could probably have been prolonged. The trial judge held that there was no testimony that the father's neglect caused or even materially hastened death. The Supreme Court really decides nothing except that the appeal was not so presented that it could decide the important public question which the State sought to have reviewed, and thereby determine and settle in this State the law applicable to cases like the one at bar. But Judge Jordan, speaking for the court, quotes with approval from cases in New York, Canada and England, in which parents have been convicted of manslaughter for neglecting sick babies, where the courts held that religious belief was no excuse for not providing medical care and attention. The decision by the highest court of British Columbia, where the father, a "Zionite," refused to call a physician for his children when he knew they had diphtheria, is stated to the effect that the person who fails to provide necessary medical attention and remedies is criminally responsible and that a conscientious belief that it is against the teachings of the Bible is no defense. Judge Jordan concludes that the question involved is one of public importance, and if there is an absence of law in this State in respect to a case like this, the legislature should promptly deal with the matter by proper legislation.

Health Work in the Philippines.—The work of the Bureau of Government Laboratories of the Philippine Islands, as shown by reports received at the Bureau of Insular Affairs, War Department, covers a vast amount of interesting and useful work. A new building, adapted to the needs of the bureau, is now about completed. It will greatly increase its usefulness and will bring the scientific work of the insular government practically under one roof and thus allow the different branches of the work to be mutually helpful. Provision has been made for housing the branches of chemistry, bacteriology, pathology, botany and entomology and for preparing prophylactic and curative serums. An ingenious method has been employed for securing an adequate gas supply. Oriental coals are deficient in gas producing qualities, and importations from Europe or America would be entirely too expensive for the purpose, and even gasolene, which is sometimes used for the purpose, was found to be unsatisfactory. The bureau, therefore, adopted the plan of preparing gas from cocoanut oil, a native product. Strong castiron retorts are brought to a red heat in furnaces and the cocoanut oil is then slowly fed into them, thus producing a very high quality of illuminating gas, free from smoke and tar. The struggle waged by the bureau against rinderpest, which threatened to sweep the islands of draught animals, was eminently successful, and the veterinarians now have a herd of about seventy-five animals in their rinderpest serum herd for the purpose of furnishing a serum with which to inoculate non-immune herds. The demand for vaccine virus has also been very great, for until the advent of the Americans no systematic effort had ever been made to vaccinate the people of the islands, and smallpox, like the poor, was always present. A large number of calves were purchased for the purpose of preparing the virus, and then sold to stock growers. The laboratory reports that it never found a case of tuberculosis when examining calves to be employed for the purpose of cultivating the vaccine virus. A plague prophylactic has also been furnished to the Board of Health in sufficient quantities, and its intelligent employment has brought down the plague cases to such a degree that the islands are now practically free from this dread disease. The cholera epidemic, which began early in 1902, threw such a large burden of routine work on the laboratory that it interfered with much original investigation undertaken by its scientists. The biological laboratory is also investigating human diseases and has in preparation a work on a method of protective inoculation against Asiatic cholera and on amœbic dysentery. The Philippine commission, desiring that the laboratory be of the greatest possible economic benefit to the people of the islands, allows the general public, for reasonable and fixed charges, to secure from the bureau analytical and diagnostic work. As a result, both the public and other branches of the Government have obtained analytical results of all kinds and of the highest scientific accuracy. Fifteen bulletins have been published by the laboratory on medical, veterinary and botanical subjects, some of which have excited wide attention. On the whole, the record of the first year's work of the Government laboratories is one that reflects credit on the Government and the men who have devoted themselves to scientific research.

American Medical Editors' Association.—The thirty-fifth annual meeting of the American Medical Editors' Association, held at Atlantic City in June, 1904, was one of the most successful in its history. The many papers presented, as well as the numerous applications received for membership, is possibly the best indication of the interest displayed in the Society.

Among the interesting papers read and thoroughly discussed were: "Proprietary and Patent Medicines," Harold N. Moyer, Chicago, Ill.; "Military Medical Journalism of the Present Day," Major J. Evelyn Pilcher, Carlisle, Pa.; "Sundown Journalism," T. D. Crothers, Hartford, Conn.; "Medical Illustrations," H. V. Wurdemann, Milwaukee, Wis.; "Medical Journalism of the Pacific Coast," Winslow Anderson, San Francisco, Cal.; "The Medical Press vs. The Modern Plague," William Porter, St. Louis, Mo.; "Reading Notices," W. C. Abbott, Chicago, Ill.; "Imitation Journalism," H. Waldo Coe.

Following an animated discussion of Dr. Porter's article relative to the use of patent nostrums, the following resolution, endorsing the action of Mr. Bok, editor of the *Ladies' Home Journal*, was favorably acted upon: *Whereas*, The public is, and long has been, suffering from the use of nostrums, and from the misuses of medicines; and, *Whereas*, the medical profession and press have endeavored by every means in their power to instruct the laity upon the subject; and, *Whereas*, some journalists either do not understand the true situation, or find it to their pecuniary gain to favor the use of nostrums and pander to the greed of their manufacturers at the expense of the health or even the lives of their dupes among the people; and, *Whereas*,

the eminent editor of the *Ladies' Home Journal,* Mr. Edward Bok, in an able and vigorous editorial on page 18 of the May number of that journal, laid the truth of the matter before his readers, thus aiding in the work of warning and educating and conserving the health and welfare of the public; be it

Resolved, That the American Medical Editors' Association approves and commends Mr. Bok for the intelligent, honest, fearless and well-grounded position he has taken, which has been thoroughly appreciated by us and by the medical profession generally. *Resolved,* That a copy of these resolutions be spread upon the minutes of this meeting, be transmitted to Mr. Bok, and be published in the medical journals throughout the country.

Dr. Porter presented the following resolution bearing upon the death of Dr. I. N. Love, an ex-president of the American Medical Editors' Association:

Resolved, That the members of the American Medical Editors' Association, while mourning the decease of Dr. I. N. Love in the zenith of his manhood and opportunities for usefulness, remember and cherish the recollection of all in his most attractive individuality that made his record so large a part of the history of this Association. *Resolved,* That a large page of our record books be set apart for the resolutions and that a copy be sent with our truest sympathy to the members of his family.

The folloging officers for the coming year were elected: President, Harold N. Moyer, Chicago, Ill.; First Vice-President, C. Evelyn Pilcher, Carlisle, Pa.; Second Vice-President, O. F. Ball, St. Louis, Mo.; Secretary and Treasurer, J. MacDonald, Jr., New York; the Executive Committee, C. E. de M. Sajous, chairman; John Punton, W. A. Young, W. C. Abbott, H. M. Simmons, C. F. Taylor and Charles Wood Fassett.

Hypnotism and Drunkenness.—At a recent meeting of the Society of Hypnology and Psychology in Paris, as reported by the *Evening Post*, an interesting report was read from Dr. Korovine, of the Moscow Asylum for Inebriates, where experiments for the cure of drunkenness by hypnotic suggestion have been carried out, upon a considerable scale, for three years. Dr. Korovine claims 22 per cent. of radical cures out of some 300 patients. He says that out of 323 patients hypnotized 84.4 per cent. did not drink any alcohol for a week, 60.2 per cent. abstained for two weeks, 33.8 per cent. for three weeks, 27.7 per cent. for more than a month, but only 3.1 per cent. for the whole time of the treatment—that is to say, for six months. He thinks that in more serious cases hypnotic suggestion to be effective must be associated with indoor treatment under restraint. Commenting on these facts, Dr. Berillon of Paris explained that when drunkards ask to be hypnotized they are generally very amenable to the influence of suggestion, but often they suddenly change and it is no longer possible to hypnotize them. In that case they have been drinking, and it is necessary to wait until they are quite sober and to treat them fasting. It is said that Dr. Forel, of the Zurich Lunatic Asylum, one of the best hypnotic authorities in Europe, no longer directs his suggestions against the drink itself, but against the habits and companions of the drunkard. He holds that it is not of much use trying to prevent a dipsomaniac from drinking until a radical change has been effected in his social surroundings.

OBITUARY.

Dr. Romeo F. Chabert, one of the oldest physicians in Hudson County, New Jersey, and for twenty years a property holder and summer resident of Asbury Park, died late last Monday at his summer home, on Seventh avenue, Asbury Park. He was seventy-six years old, and for forty-eight years had practised medicine and surgery in Hoboken. He was a member of the New Jersey State Medical Society, the founder and consulting surgeon of St. Mary's Hospital, Hoboken; consulting physician of the Bayonne Hospital, and for many years a member of the Board of Managers of the State Hospital for the Insane at Morris Plains.

CORRESPONDENCE.

OUR PARIS LETTER.

THE QUESTION OF HEALTHY DWELLINGS—A SUPERVISORY LAW IN FRANCE—EXCESSIVE OVERCROWDING OF BARRACK-LIKE TENEMENTS—CHEAP BUILDING SOCIETIES ON THE INCREASE—GERMANY FAR AHEAD IN THIS MATTER, OWING TO PROTECTION OF THE STATE—ROTHSCHILDS' BENEFICENT PLANS.

Paris, France, July 21.

The donation of ten millions of francs that has lately been made by the Brothers Rothschild with a view to bettering the conditions of the working classes by the creation of cheap and healthy dwellings, as well as the inauguration of the first building constructed by the "Society of Hygienic and Cheap Dwellings," have drawn public attention in France to the interesting problem of hygiene in the houses of the poor.

In other countries, as, for example, America, England, Germany, legislation rules the condition of the habitations of the working classes; in England rigorous laws permit the pulling down and expropriation of whole quarters when that is necessary for public salubrity. In Germany certain municipalities, as at Ulm, Stuttgart, Carlsruhe, build model dwellings for workmen, whereas in France the initiative has not been taken by the public authorities, and the only effort of the legislator has merely been a law or bill of encouragement, dating from 1894. This law oversees in each district, or department, the formation of local committees whose mission it is to encourage the construction of salubrious houses either for private persons or for societies, with a view to letting them out to workmen or employees hiring on the proceeds of their labor or on their wages. A committee composed of several deputies and senators, members of the "French Institute," presided over by the Minister of Commerce, and with Mr. Jules Siegfried, a former cabinet minister, and Eugene Gouin, Senator, as vice-presidents, examines the work done, inspires the work, and draws up a yearly report to the President of the Republic.

Besides this organ of official encouragement there is another, but due to private initiative, the French Society of Cheap Dwellings, formed after the Congress of 1889, and whose honorary president is Mr. Siegfried. The building, inaugurated in the Rue de Tretaigne at Monmartre, is a five-storied one and includes twenty small flats, each containing three rooms besides a kitchen and water closet. On the ground floor there is a library and a general store. Everything pertaining to modern hygiene is observed in the building; thus there is no useless decoration, the floors are not parqueted, the moldings are rounded, the walls washable. It is on this model that other buildings are to be constructed, which will serve to lower the terrible mortality incident to its enormous, overcrowded and barrack-like houses in which workmen and their families take their repose after their day's work. The mortality among this class sometimes reaches the high proportion of 80 per 1,000 per year. That is the figure stated by Mr. Siegfried,

who so regrets the want of even elementary comfort so necessary to both town and country populations.

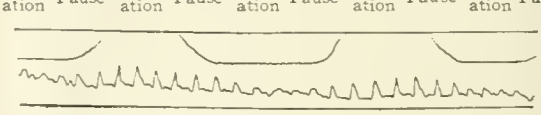
To combat this state of things two solutions are proposed. The erection of new, low-rented houses, such as that of which we have just spoken, or else the adoption of Mr. Cheysson's plan, the cleansing and purifying of old houses, which would be less expensive. The movement in favor of house hygiene dates back about fifty years and was due to Prince Albert in England and to Mr. Jean Dolfus, of Mulhouse, in France, but it has only become important since 1885, owing to the efforts of Mr. Jules Siegfried, of George Picot, the perpetual secretary of the Academy of Moral and Political Sciences, and of Eugene Cheysson of the Institute, who showed up the existing peril, as well as the duty to be performed. In addition to the committees which favored by the law, there are 109 societies devoted to the subject of the erection of economical dwellings, of which fifty-six are coöperative and fifty-one civil societies. Moreover, in France, cheap-building societies have offices in seventy-seven towns. There are twenty-one societies in Paris, three at Douai and Marseilles, two at Calais, Rouen, Tours, Amiens, Lyons, Anjers, Maisons, Alport and Algiers. All have nearly the same aim, viz., the purchase of ground and erection of cheap dwellings either self-contained or collective. Unfortunately the existing building societies have, for the most part, been founded with insufficient funds, while in England the question has been considered as a simple business affair and the English Mutual Aid Societies, very rich, have found there a convenient means of placing their capital, while in Germany (besides the philanthropic foundations which exist there as in England) special resources are available for economical dwellings, derived from obligatory insurance. In France this work has had to be protected by law. Laws of 1894 and 1895 granted to these enterprises certain advantages in the form of fiscal indemnity and lowering of taxes, and again, savings banks have been authorized to employ their personal revenue and the fifth of their fortune in building or acquiring cheap dwelling houses.

Private initiative and, in particular, that of the Civil Society of Cheap Buildings has, with this aim in view, founded societies of credit able to negotiate with building societies or to guarantee them at the "Caisse des Depots et Consignations." The foundation of Messrs. Alphonse, Edmond and Gustave de Rothschild, which in France will be the pendant of the Peabody Foundation in England, will, by means of buildings that are to be erected, be of efficacious help to workmen. This endowment of ten millions is to be employed in building houses with cheap flats for the Parisian population. The revenues are to be employed to give grants to those initiatives of special interest to the working classes.

REMARKABLE PULSE TRACING.

To the Editor of the MEDICAL NEWS:

DEAR SIR: I enclose a pulse tracing showing a rhythm to which I can find no reference in the literature at my disposal. As the tracing shows, the pulse wave becomes markedly smaller during expiration and the post-expiratory pause. It is thus a phenomenon, the opposite to the paradoxical pulse, and in lieu of a better term, I have applied the designation, "The anti-paradoxical pulse" to what it represents. It occurred in a patient suffering from an aneurism of the innominate artery and the diminution of the pulse wave was brought about by the collapsing chest pressing upon the aneurismal sac during expiration. When admitted to hospital this rhythm was very evident to the finger during ordinary breathing. As his heart gathered strength from the rest, it was only apparent during deep respiration and later disappeared entirely. The



Tracing of right radial pulse during deep respiration. Patient holding his breath both at end of inspiration and of expiration.

left radical and left carotid pulses were regular. It seems rational to suppose that such a pulse might be present in similar cases of innominate aneurism associated with a weakened heart.

SAN FRANCISCO.

SOCIETY PROCEEDINGS.

BRITISH MEDICAL ASSOCIATION.[1]

Seventy-second Annual Meeting, Held at Oxford, England, July 26, 27, 28 and 29, 1904.

FIRST DAY.

The Oxford Medical School.—The history of the origin and development of the Oxford Medical School was made the subject of the address of the President, William Collier, M.D., of Oxford. It was in 1868, he said, that the last meeting of the association had been held at Oxford, and the desire to compare the status of then and now had suggested to him his topic.

Twenty-four years ago, in 1880, he said, when this Association held its annual meeting at Cambridge, the then President, Sir George Humphry, in one of the most eloquent and forcible addresses ever given to the Association, used these words:

"Has there not through the whole period of our academic history been enacted a divorce, a most unnatural divorce, between body and mind—that is to say, between the nurturers of the one and the cultivators of the other? Has not Cambridge more than any university, with perhaps one exception, banished medicine from its walls and the men of medicine from its schools? Can good reason be shown why medicine has been allowed to profit so little by the accumulated liberality of many generations, which has given such impulse to art and literature, to classics and theology, mathematics and philosophy, to astronomy and logic?"

He pointed out that originally the Faculty of Medicine had been placed on par with those of Divinity and Law, and the provisions for teaching and graduating in all these faculties had been made alike.

A little later Humphry gave what was probably the correct answer to his inquiry. For he showed that the College of Physicians in London, founded by the influence of Linacre, with the privilege of licensing practitioners throughout the kingdom, became in time the successful rival of the old Universities of Oxford and Cambridge. As London grew in size and importance the influence of its college increased, and in a short time little was left of the universities beyond the function of giving a preliminary training to the few who could avail themselves of it. In no other European country are there competing corporations similar to our Colleges of Physicians and Surgeons, having power to grant licences to practise. In other countries the universities are the only avenues to medicine.

Revival of a Medical School in Oxford.—Why should not the Universities of Oxford and Cambridge take their proper share in the training and education of medical students? This question had for some years previously occupied the thoughts and minds of many earnest men at both universities. Science had already obtained a sound footing. At Cambridge the Honor School of Natural Science had been established as far back as 1851, at Oxford in 1853, while at Oxford the University Museum—the center for scientific work—in which our Sectional meetings will be held this week, had been built, thanks very largely to the influence and exertions of the late Sir Henry Acland.

So long ago as January 5, 1878, an anonymous correspondent, signing himself "A Member of Convocation," wrote a long and bitter letter complaining of the way in which the study of medicine was entirely overlooked at Oxford. As a medical school Oxford, he declared, had within the preceding quarter of a century entirely ceased to exist. No teaching in the preliminary subjects of medicine was being given, and the medical faculty had recently lost even its nominal existence, and now appeared under the head of physical science and mathematics. He attributed this decadence largely to the influence of the then Regius Professor of Medicine, and to the Professor of Physiology. They were ably defended by several of their old students, who showed how much the teaching of natural science at Oxford owed to their personal efforts. The controversy on medical teaching at Oxford was carried on with vigor for many months by many writers, and while all, or nearly all, were in favor of making adequate provision for the teaching of anatomy and physiology at the university, some were most anxious to establish a complete medical school, declaring that in many of the most illustrious medical schools in Germany the hospital population was not larger than it was at Oxford.

A little later another petition was drafted on very similar lines by an entirely different body of men, and was sent to the commissioners who were at the time engaged in investigating the affairs of the university.

In November, 1882, Professor Burdon Sanderson was appointed to the newly founded Chair of Human Physiology and Histology at Oxford, a first step towards the establishment of medical education in Oxford on modern lines.

Development.—Having elected a professor of physiology, it was found necessary to build laboratories and class rooms for the purpose of teaching, and on June 5, 1883, the members of Convocation were asked to grant a sum of £10,000 for this purpose. The resolution met with keen opposition, partly on the ground that vivisection would be practised, and partly on the ground that the expenses were beyond the existing resources of the university. The resolution was carried by three votes.

In the same year (1885), he said, the Faculty of Medicine, which had been merged in natural science, was recreated, and Mr. Arthur Thomson, Senior Demonstrator in Anatomy in Edinburgh University, was elected Lecturer in Anatomy. It needed a man of resolution and fixed purpose to cope with the situation, for when he took up his work in Oxford Mr. Thomson found himself with three students and a small wooden shed in which to teach anatomy—a great contrast to his Edinburgh experience. A sum of money was immediately collected by members of the university interested in the development of the school, and a small temporary lecture room and a dissecting room were built. In the following year the curators of the University Chest built, at a cost of £500, a temporary iron-roofed building with rather more accommodation. By 1891 the lecturer's class had grown from 3 to 67. A sum of £7,000 was now asked and obtained from the university to provide a permanent home for the teaching of human anatomy, and the present excellent building, in which the Section of Anatomy will be held, was built. In a year or two, largely owing to the success of Mr. Thomson as a teacher, the lectureship was converted into a professorship. In 1886 a most important statute was passed, by which students in natural science were exempted from the first public examination in classics known as Moderations. This measure enabled students of medicine after passing their preliminary examination known as Responsions, which might be passed before coming into residence, to devote their first year in Oxford to the study of the preliminary subjects in natural science, and so another and most important barrier to the establishment of a medical school disappeared. In 1891 Sir Henry Acland, who had always interested himself in the study of pathology and bacteriology, inaugurated a new department in bacteriology, and appointed, first, Dr. Menge, of Munich, to take charge of it, and later, in turn, Dr. Bertram Hunt and Dr. Ritchie.

In 1899 a generous medical student, Mr. Ewan Frazer, offered the university a sum of £5,000 toward the expenses of building a pathological laboratory. This sum was accepted, the university at the same time agreeing to supplement it with another £5,000, and to make an annual grant of £250 for upkeep. In October, 1901, the new Pathological Laboratory was opened.

Influence of the School.—For some years a considerable number of medical graduates have been passing forth into the larger world after spending three or four of the most impressionable years of their lives at one or other of the two universities. Have they benefited? The majority of these graduates if appealed to would declare with no uncertain voice that they recognized fully that their mixing with men of their own age, who were taking up other subjects for their life-work, and interesting themselves in other mental pursuits, had done much to widen their own general culture, and to develop in them interests outside their own professional work. Has the university benefited? Yes. The establishment of the medical school on a modern basis has introduced into the university a body of students starting their university career with a definite object in view, and compelled by the very nature of the case to lead a steady, strenuous life, for no student can hope to pass his professional examinations without a due amount of steady work.

But to his mind the greatest advantage to be noted has been the influence the university student has had on the other medical students of the great metropolitan schools. All of us are familiar with the Bob Sawyer type of medical student as depicted by Charles Dickens—that is to say, all are familiar with him in fiction—but as a living type he has for many years ceased to exist. Many can remember the time when any more than usually disgraceful outbreak of rowdyism in London was invariably attributed, rightly or wrongly, to medical students. But this is a matter of the past. The medical student of a quarter of a century ago undoubtedly bore a very bad character in the eyes of the public; he no longer does so. Why the change? Largely because of the influence of the university graduates who have come among them.

Earlier Benefactors.—From Oxford of to-day to Oxford of the past, a few of Oxford's greatest men, members of the profession, who have been associated with the university, were mentioned.

Linacre, who at the age of twenty-four, in 1484, was elected a Fellow of All Souls, and was incorporated a D.M. of the University on his Padua degree, is first to be thought of. While at Oxford he seems to have devoted most of his time to giving lectures in physic and to the teaching of Greek. Not only was he a profound scholar and a successful physician, but he was also a member of the clerical profession—indeed, the last few years of his life were entirely devoted to clerical work. He bequeathed considerable sums of money to both Oxford and Cambridge for the purpose of encouraging the teachers of medicine. The Linacre Professorship of Comparative Anatomy is a reminder of one of our oldest and most distinguished benefactors. It was mainly due to Linacre's efforts that the Royal College of Physicians of London was founded in 1518, he being elected the first president. It was probably due to his influence, too, that a statute was passed in Henry VIII's reign that no person should practise as a physician or surgeon until examined and approved by the bishop of the diocese in which he lived, who was to call to his assistance expert persons in the Faculty.

For some years Harvey, the discoverer of the circulation of the blood, dwelt at Oxford, where he worked at anatomy and made many dissections. He was incorporated a D.M. of the University, and in 1645 by royal mandate was made Warden of Merton College, but did not retain the post long, as the following year, after the surrender of the city to the Parliamentarians, he returned to London.

It was while Harvey was at Oxford that another great anatomist who studied under Harvey was preparing himself for future fame—Thomas Willis, well known to all by his description of the anatomy of the brain, and more particularly by the circle of Willis. Willis was born of Oxfordshire parents within a few miles of our city, and for many years practised his profession in a house opposite Merton College.

Associated with Willis was Christopher Wren, the architect of St. Paul's Cathedral. Born in 1632, Wren left school at the age of fourteen, and was engaged by Sir Charles Scarburgh to act as his assistant and demonstrator at his lectures on anatomy at Surgeon's Hall, London. Three years later, at the age of seventeen, he was entered as a fellow-commoner at Wadham, and at twenty-one was made a Fellow of All Souls, and at twenty-eight Savillian Professor of Astronomy. It was while at All Souls that he made elaborate drawings to illustrate Dr. Willis's work on the anatomy of the brain. In 1679 he made experiments which led him to the invention of a method for the transfusion of blood from one animal to another. It was at the age of about thirty he began to follow the profession of architecture, and one of his first works was this Sheldonian Theater, the first stone of which was laid in 1664 and completed five years later. At the age of nine he was capable of writing an elegant Latin letter to his father, but it was science and mathematics that attracted him. A splendid mathematician, a great experimentalist, always working out the most difficult scientific problems, a distinguished astronomer, and a famous architect all combined in one. No wonder that Barrow described him as a boy a prodigy, as a man a miracle, nay, even something superhuman. He died aged ninety-one years.

The greatest benefactor of the university was John Radcliffe, who was born in 1650 and died in 1714. For nine years he practised as a physician in Oxford, and we are told that he incurred the anger of the older practitioners in the town because he paid so little regard to professional conventionalities. In 1684 he moved to London, and his apothecary tells that he had scarcely been in town a year before he was earning more than 20 guineas a day. His lively conversation, it was said, soon made him the most popular physician in London. He succeeded more by his ready wit than his learning, for while at Oxford his library consisted of some phials, a skeleton, and a herbal. In 1692 he lost some £5,000 owing to the capture by the French of a ship in which he was interested. When his friends condoled with him he replied that it did not matter, for he had only to go up 250 pairs of stairs to make himself whole again. If this be true the physicians' fees in those days would seem to have been very much higher than at present. At any rate, his philosophical way of putting up with a financial loss was admirable—a little more work would put him right again. During his life he gave largely to his old college and to several charities, and at his death he left by will his Yorkshire estate to the Masters and Fellows of University College for ever, to be held in trust for the founding of two Radcliffe traveling Fellowships, the overplus being paid for the purpose of buying perpetual advowsons for the college. In addition he left £5,000 for the enlargement of the college and £40,000 for the building of a medical library. With money derived from his estates two other buildings were erected in this city by his trustees, the Radcliffe Infirmary and the Radcliffe Astronomical Observatory, and money was further granted towards the building of the College of Physicians in London.

Thomas Sydenham (1624-89), who has always been regarded as one of the chief masters of English medicine, was also connected with the university. His career at Oxford was certainly a checkered one. At the age of eighteen he entered as a fellow commoner at Magdalen; a few months later he joined the Parliamentary forces and fought against the Royalists; four years later, 1646, when Oxford and the other royal garrisons surrendered, he resigned his commission, and was on his way to Oxford when he chanced to meet with Dr. Thomas Coxe, who was attending his brother, and who persuaded him to take up medicine. He then joined Wadham College, and the following year was elected to a Fellowship at All Souls. In 1648 he obtained his degree of B.M. in a very irregular manner, as he was created B.M. by command of the then Chancellor of the University without having taken a degree in Arts and with little knowledge of medicine. For a time he studied at Oxford under the Regius Professor of Medicine, whose lectures, we are told, consisted merely in reading the ancient medical classics. Again he joined the army, and became a captain of a troop of Parliamentary Horse. On one occasion he was left on the field of battle among the dead, and lost, as he tells us, a great deal of blood. On another occasion he nearly lost his life at the hands of a drunken soldier, who broke into his bedroom at night and discharged a pistol at his breast. Fortunately the soldier's left hand was interposed and was shattered by the bullet, while Sydenham escaped unhurt. Having again retired from the army he studied medicine at Montpellier, and a year or two later began practice in London. In 1676, at the age of fifty-two, he incorporated as M.B. at Pembroke College, Cambridge, on his Oxford degree, and immediately took the M.D. of that university. It is supposed there were political reasons for his not taking the Oxford degree. By his methods of studying disease and by his masterly description of diseases Sydenham is admitted to have made an epoch in medical science. In 1894 a life-sized statue of Sydenham was presented to the University Museum by Sir Henry Acland and others.

He then went on to speak of present benefactors, and

closed with a forecast of the future of the school and a short reminiscence of the earlier meetings of the Association at Oxford, as follows:

"To-day our association numbers over 19,000 members, and we are expecting more than three times the number who visited Oxford in 1868. More than this—and it is, I think, a matter for hearty congratulation—the influence of our association has grown world wide, for since 1868 branches have been formed throughout India and in nearly all of our colonies. This truly remarkable growth of our association in magnitude, power and influence has been due to the fostering care and unremitting labor of many workers. Into our hands they have entrusted a great inheritance, and it will be our duty to see that no negligence nor unwise and ill-considered action on our part tend in any way to jeopardize its further growth and development and power for usefulness."

Address in Medicine.—Sir William Selby Church, Bart., President of the Royal College of Physicians of London, spoke "On Our Sanitary Needs, with Special Reference to the National Health."

Medicine, he said, having for its object the mental and bodily health of mankind is closely interconnected with the varying circumstances that bear on the conditions under which a people lives. The prosperity of the nation, the conditions under which the labors of the population are carried on, the state of commerce and the arts and sciences, all react on the health of the people, and nothing which concerns the life of the nation is foreign to the subject. Every advancement in science and its application to the arts has a bearing on medicine. To pure science it is directly indebted for means by which the various organs of the body can be examined, the presence of disease demonstrated, the changes in our bodies accompanying disordered health recognized, and, perhaps more important than all, the exact methods of science point out the way in which the more complex questions presented in living bodies should be studied.

It was in the year preceding the Oxford meeting that Lister read at Dublin his paper on the "Antiseptic Principle in the Practice of Surgery," founded on the results of his treatment of compound fractures, abscesses and wounds during the preceding three years. It was at this time also that the infectivity of tuberculous matter began to be generally recognized; twenty years before, Klencke had produced tuberculosis of the lungs and liver in rabbits by inoculation with human tubercle, but he did not pursue his investigations, and his experiments attracted little notice, and it was not until Villemin's work in 1861, and the account of his numerous and careful experiments published in 1868, that attention was again drawn to the subject. Villemin's work was carried on by Sir J. Burdon Sanderson, late Regius Professor of Medicine in this university, who explored and demonstrated the channels by which the tuberculous process is disseminated within the organism, yet many years had to elapse before Koch in 1882 demonstrated that the presence of the tubercle bacillus in all tuberculous degenerations was the essential element.

Growth of Bacteriology.—It was, he said, the adaptation of Pasteur's work and discoveries to medicine, and Koch's demonstration of the bacillus of tubercle in 1882, which led to the revolution which has taken place in conceptions of the nature and cause of many forms of disease, and he drew an interesting picture of Sir William Gull's descriptions of disease processes. How much more hopeful, he said, is the outlook now than when Gull said: "It is now universally acknowledged that the art of medicine is all but powerless in controlling the large class of diseases called zymotic! It may be there do not exist nor may ever be formed by art antidotes to their poisons. But should it be otherwise my duty at this moment still seems clear—that I ought not to stir up your minds to search for such secrets of nature. Upon this search too much time has already been wasted, and an incalculable amount of life has been lost. Specifics will no doubt continue to be sought after, but preventive medicine will more largely obtain the suffrages of the best informed members of our profession. Truly, as he says in another place, "the knowledge which seems exhaustive to-day, may in the changing circumstances of the world be defective to-morrow." For it now seems probable that most, if not all of these diseases, as we already know of some, bear with them their own antidote, and that as Sir John Sanderson has said "Every injurious substance which is capable of being assimilated (in the physiological sense) by a living cell is also capable of exciting in it an abnormal reaction antagonistic to the first."

Internal Secretions.—Another most important step onward in physiological knowledge and its application to the treatment of disease was made when the connection existing between that group of symptoms known as myxedema and disease of the thyroid gland was pointed out. Sir William Gull himself, in 1873, was the first to draw attention to the cretinoid state supervening after adult age, but it was from the researches of Ord, Reverdin, Kocher, Horsley and Murray that the existence of what are spoken of as internal secretions of glands was suspected and proved. Neither in diabetes nor in morbus Addisonii has the administration of the pancreas or the suprarenal glands been followed by any marked or constant beneficial effect on the disease. The researches of Schäfer and Oliver have proved the physiological action of the extract of the suprarenal glands to be both constant and powerful, and further researches may lead to a better knowledge of the physiological functions of the internal secretions and enable therapeutic use to be made of them.

Tropical Medicine.—In other lines of research the progress made is not less remarkable. The ancients were well acquainted with the commoner forms of intestinal worms, although they were ignorant of the remarkable phases presented in their development. They have left full and accurate descriptions of the clinical symptoms produced by them and the means which should be adopted for their cure. Slowly and gradually the natural history of malaria and yellow fever has been worked out. Already the work done, mainly under the auspices of the Liverpool and London Schools of Tropical Medicine, has begun to bear fruit not merely by increasing knowledge of malaria and certain other forms of tropical disease, but by having in the short space that has elapsed had a marked influence in diminishing sickness and mortality in places which were so deadly to European life, that trade could hardly be maintained with them. Nor is it only in these hot-beds of fever that beneficial results have been obtained, as Professor Boyce's account of antimalarial measures taken at Ismailia shows. The result of the sanitary work put in action by the authorities of the Suez Canal has been eminently satisfactory. The attacks of malaria in a population consisting of about 1,900 or 2,000 Europeans and 7,000 natives have fallen from 2,089 in 1897 to 209 in 1903, and the mortality has correspondingly lessened. These highly satisfactory results have been obtained at comparatively small expense, the Canal Company having expended £4,400 in filling up and draining the marshy ground, whilst the special antimalarial forces—the Drainage and the Petroleum Brigades—

have together cost £720 a year, figures which contrast most strikingly with a previous "expenditure of £15,000 on works designed with the intention of improving the sanitary condition of the town and £13,000 in medicine and medical attendance," without the production of any beneficial results. The mystery surrounding the sleeping sickness of Africa has been partially dissipated by the discoveries of Castellani, Bruce and Nabarro, and the remarkable life-cycle of the trypanosoma is in a measure unraveled. A similar chain of events appears to occur in Texas fever, and probably in other morbid states the lower forms of animal life play a much more important rôle than is yet recognized. Recent investigations by Leishman, Donovan, Ross and Christophers tend to show that the condition of chronically enlarged spleen and cachexia we have been accustomed to ascribe to malaria is more probably dependent on another distinct microorganism.

Preventive Medicine.—The speaker then spoke of the outcome of the results of preventive medicine. He first contrasted the conditions as seen in Ancient Greece, quoting Plato. Roman sanitary science remains for the most part an unopened chapter in medicine, but it is certain that in the larger cities some municipal organizations similar to, if not identical with, those which had been in force in earlier Greek times were present. Before the time of Antonius Pius (A.D. 136) recognized medical practitioners were exempt from ordinary civil obligations and local taxation, but their numbers had so largely increased by his time that it became necessary to limit the number of recognized practitioners in each city who should enjoy this immunity; and Pliny, who seems to have had nearly as bad an opinion of the profession as Cato, complains that the law unduly safeguarded physicians, and that they alone could kill a man with impunity. The better regulation of the profession in this country may be said to date from the institution of the Royal College of Physicians in 1518, which was entrusted with the general supervision of all persons not graduates of the two English Universities of Oxford and Cambridge who should practise physic throughout England, and to the granting of a charter by Henry VIII. to the Barber-Surgeons twenty-two years later.

Medical Legislation.—In an extremely interesting manner he then traced the development of the humanitarian spirit throughout the Calvinistic times and showed the connection between the greatly increased interest in the humanities with medical legislation. These suggested the Anatomy Act of 1832 and the Medical Act of 1858.

Poor Law and Public Health Legislation.—Contemporaneously with the awakening of public opinion to the necessity for a reform in the constitution of the medical profession, by which the public might be able to discriminate between those who were and those who were not legally qualified to practise, the need for increased legislative power for sanitary purposes was recognized. The public mind had been aroused by the ravages of cholera, which spread through the land in 1831-32 and to a less degree in 1848-49; while the revelations of the conditions under which the laboring poor were living contained in the reports of Drs. Neil Arnott, Kay, Southwood Smith, Mr. Chadwick, and others to the Poor-Law Commissioners appealed to all but the most thoughtless, and prepared the way for sanitary legislation.

The dissolution of the monasteries and other religious foundations in the sixteenth century led to the whole country being flooded with pauperism, for however self-indulgent the ecclesiastics may have been, they had always exercised supervision over the poor on their estates, and administered relief as required to those who were in the employment of the religious houses or of their numerous tenants. This deplorable condition of the nation gave rise in the early years of Elizabeth's reign to the present Poor Law, and during her reign, and that of her immediate successors, very stringent Acts of Parliament and municipal regulations were passed not only for the removal and prevention of nuisances, but also dealing with vagrancy and mendicity, and provision for the relief of pauperism and the care of the impotent poor. From that time onward numerous local Acts on a variety of subjects bearing on the National Health were added to the statutes, but no comprehensive scheme was instituted until we come down to the Victorian Era, and the passing of the Public Health Act of 1848 may be taken as the date of the rise of a fresh branch of medicine—Preventive or State Medicine. It was then that the State publicly recognized what Hobbes two hundred years before when writing "of the Commonwealth" had indicated as the function of the governing power. The health of the people, both bodily and mental, is the principal asset of the nation. Without a vigorous and energetic population no nation can make progress, and coincident with the cessation of progress is the commencement of decadence.

Speaking on several questions of Public Health he rehearsed the specifications of the Public Health Law, spoke of the Ineptitude of the Treasury Reports and commented on the Duties of Local Boards and Medical Officers.

Need for Supervision of the Sale of Foods.—The need for such increased supervision was forcibly brought to the attention of the commissioners appointed to inquire into arsenical poisoning. At the present moment there are no means by which the officers, medical or other, of County, Borough, Urban or District Councils who are responsible for the local administration of the Acts relating to the sale of food can enter the premises and obtain information concerning the nature or foodstuffs or the process of their manufacture.

The needs for sanitary food supervision were recognized, and he dwelt particularly on the folly of permitting patented foods to be placed on the market without proper chemical investigation. At present, he said, the maker of a foodstuff sold under a fancy name—Grape Nuts, Force Food, etc.—is under no obligation to submit to any authority the composition of its ingredients. It is only after the foodstuff has been placed on the market that any control can be exercised by samples being taken for analysis, which, although showing the absence or presence of deleterious matter, gives but little guide to the suitability and value of the preparation as a food. The enormous bulk of these fancy and largely advertised foods on the market, both home made and imported, renders it essential that further power in the supervision of food should be placed in the hands of the health authority.

Rural Hygiene.—The necessity for sanitary regulations being so much greater in large towns with their dense populations, manufactures, and difficulty in disposing of their refuse naturally led to the earlier efforts in the direction of improved sanitation being especially directed to their most urgent needs, and hence has arisen that the methods of sanitation applicable to large towns have been accepted by the public as the only ones, and are imitated in rural districts to the great loss and harm of the community. It is greatly to be regretted that Mr. Chadwick's doctrine that not only domestic sewage but that all sorts of refuse are best removed by the scour of running water has received

such general adoption. Whilst the advantages of the present system of sewerage, although ruinously expensive, is undoubtedly very great in our large towns, and must perhaps be perpetuated, it is not in accordance with common sense that it should be recklessly applied throughout the country. The disposal of the liquid sewage not only of our large towns, but of our villages, villa residences, and country gentlemen's houses, has become a most difficult problem for modern sanitarians. No one has any more justification in injuring his neighbor by wilful or culpable negligence of sanitation, or by the means he takes to protect himself from the evils he has created, than he has in appropriating his neighbor's goods or trespassing on his premises. "In rural and semirural districts the individual ought no more to ask others to keep him clean than he asks others to feed him or clothe him." The conscience of the public and of the individual needs awakening to the immorality of injuring the public weal for private convenience. We daily see instances of small towns and villages expending vast sums of money in systems of sewers and sewerage works. A system of sewerage necessitates a constant water supply far in excess of the needs of the inhabitants for domestic use; it introduces a source of danger of pollution for the springs and wells of the locality, and renders necessary the introduction of waterworks to supply uncontaminated water—if, haply, such can be found—brought, it may be, from a distance, and entails a heavy and permanent charge on the locality. The interest of the money thus spent would in many instances provide for the necessary expenses which a proper system of scavenging would entail.

He closed with some remarks on Urban Hygeine which bore more particularly on the problems in London.

(To be Continued)

NORTH BRANCH PHILADELPHIA COUNTY MEDICAL SOCIETY.

Stated Meeting held May 12, 1904.

The President, Samuel Wolfe, M.D., in the Chair.

Physicians' Bookkeeping.—Dr. Mordecai Price read a paper with this title. He stated that in the early years of his practice he had tried almost every kind of book for the purpose on the market, purchasing a new kind almost yearly, which became very expensive as well as annoying, after which he finally began keeping merely a list of calls, in book form, which were afterward entered separately, visit by visit, in a ledger, each patient being given a page, the transferring being done either at the end of a day or a week. This method he felt was incomparably better than the book ruled thirty-one spaces (one for each day of the month), as the latter gave no room for memoranda, while in the ledger one could enter in detail the time consumed, particulars of services rendered, etc. With this method, the patient's account is concentrated, the quarterly sending out of bills is much facilitated, and if a patient asks for an itemized statement, it can be rendered in a very short time; and no matter how long standing the account, it is of easy reference. He considered this method was one that would be sustained in a court of justice, citing an instance in which he had operated on a difficult case of gall-stones, the patient dying; he was compelled to present his bill in the Orphans' Court, and the judge questioned the amount thereof. With the ledger kept in this form, he was able to state exactly the character of the operation and the difficulties encountered, with the result that his bill was allowed. In reference to collecting bills by legal measures, he felt, as a rule, there was very little accomplished thereby.

Dr. L. W. Steinbach felt that the method outlined by Dr. Price would not be sufficient in court, as he stated that every entry must be made first in a daybook. His method is to keep a visiting list, with each visit to be made marked with a dot, and when the visit has been made he makes a stroke in place of the dot. In addition, he carries a prescription blank, put up in pad form with a stub to it, on which he enters a brief history of the patient's condition, the day, date and hour, at the time of the visit; the work at the office being entered in the same manner on a sheet, but a little more fully. The entries from these blanks are afterwards transferred to the ledger. He recommended that bills be sent out every six months (not more frequently than every three months), believing that this was ample time for the regular patients, and that most of the transient patients who would pay paid as they went along. He believed that the best method of collecting was to have accurate bookkeeping and send out accounts every six months, recommending the regular commercial double entry bookkeeping. With the books kept in this manner, an itemized statement can be furnished in very short order, if requested. He also laid stress on the importance of accurate history keeping.

Good Mode of Collecting.—Dr. Wilson Buckby stated that it was a notorious fact that physicians were the poorest bookkeepers in the city, and emphasized the importance at the present time, with the large increase in the number of physicians, of having the accounts kept in such a manner that they would be sustained in court. He did not feel that Dr. Price's method would be sustained in the courts, as he did not view it as a book of original entry, and recommended a combination daybook and ledger, wherein would be enumerated the detail of the services, the charge, the time spent, and expense to which the physician was put for apparatus, etc. He also referred to the fact that hieroglyphics, such as "O" for office visits, or a dash or cross, etc., indicating visits, would be entirely excluded, the requisites being that it must be a book of original entry in plain writing. He believed that in many instances the doctor was his own best collector, and that in a practice of about a quarter of a century he had had two collectors. The method of the first was to go from house to house and if they could not pay him anything get them to name a date when he would call, at which time he was sure to be on hand. The method of the second was quite similar. He stated that since discontinuing the driving and going out at nights except in cases of urgency his practice had materially decreased.

The Legal Way.—Dr. I. C. Gerhard stated that he had frequently been called into the Orphans' Court to prove his claim against a decedent's estate, and that he felt the subject of physicians' bookkeeping resolved itself into three heads: (1) The easiest way to keep books; (2) the legal way, and (3) the easiest legal way. He stated that there was no law on the statute books requiring that the books be kept in a certain way, and also that he did not think the judges desired to be exacting, the requirement being that the book should contain a daily entry of each visit, with the name of the patient and list of the medicine furnished, with the price which custom has fixed for the service. He stated that he had a claim ruled out in the Orphans' Court which had been kept in a thirty-one column book, and that in the same case an iceman had merely presented slips of paper and had his claim admitted. He recommended that a page be devoted to each patient, in which the services, etc., be entered in detail, and that the bills be sent out monthly; and believed very good results would be attained by this method.

Dr. J. Cardeen Cooper related an instance in which he had a bill reduced in the Orphans' Court from $5 a visit to $2 a visit, the judge ruling that that was the customary fee in this city, notwithstanding that the patient had previous to his death paid him $5 a visit, as the book showed no evidence of the acquiescence in such a fee by the patient.

Dr. Henry Beates, Jr., referred to the necessity for the books showing the name of the party to be charged, the name or member of the family to whom the services were rendered, date and services in detail, charges, etc., without which the books would be useless in a court of law.

Dr. A. Bern Hirsh stated that he had talked with a legal gentleman of large experience in Orphans' Court work, and that in order to secure the introduction of the books, the entries must be able to speak for themselves; in other words, the entry in the book of original entries should contain the name of the person responsible for the account, the date, the place where the service was rendered, the name of the patient, the nature of the illness, the nature of the treatment, and the charge. He called attention to the fact that the loose-leaf ledger had been decided to be legal, and believed that this method with a convenient ruling would be a timesaver to the physician. He exhibited some sample pages thereof.

Monthly Bills.—Dr. Louis Jurist stated that he had never attempted to collect a bill legally, and felt that the standing of the professional man in this country was too commercial. He believed that the charge should be regulated according to the circumstances of the patient. He did not approve of attempts to collect bills legally; and believed that the best result would be obtained by keeping the books posted up regularly, sending out bills once a month; and to perfect strangers, so soon as the services are rendered.

Dr. Walter L. Pyle deprecated the method of a "per visit" charge, and believed that the bill should be regulated, (1) by the amount of service rendered, and (2) by the circumstances of the patient. He believed the bill should be sent "For professional services rendered," and did not believe much success would be attained by going into court to collect a bill, with the exception of the Orphans' Court, with which latter, being an ophthalmologist, he had had no experience.

Dr. Wendell Reber felt that better results would be attained by sending out bills more frequently, believing that they should, excepting in special cases, be sent out monthly, while many of the general practitioners only sent them out once in two, three or six months. He referred to a case in which he had rendered a man a bill for services rendered to his wife and child, at the end of the month, and that this man requested that this be done in the future at any time any services were rendered to any of his family.

Send Out Bills Regularly.—Dr. A. M. Eaton felt that many physicians were very reckless in the matter of sending out bills, as many sent them out only semi-annually, whereas he felt better results would be obtained by being more frequently rendered. He believed that they should be rendered at not longer intervals than three months. He referred to the case of a physician who asked a friend to loan him $100. The friend requested that he allow him to go up to his office and make out some bills for him, which was done, with the result that bills for $300 were made out in less than ten minutes, over $150 of which was paid in five days. He referred to the immense amount of money which was lost by the profession. He also referred to the large number of people who were able to pay who sought free treatment at clinics, etc., which he felt should be prevented if possible, and also the people who make a practice of not paying the Doctor's bill. He believed that the formation of an association with the support of the county society, for the collection of accounts, with collectors personally calling on the debtors, would be of much value.

C. W. Van Artsdalen, Esq., of the Philadelphia Bar, stated that a book to be admitted in evidence in the courts need not be in any particular form, so long as it possessed the requisites of a book of original entry, which were (1) that the entries be made at or about the time the services were rendered; (2) the date of the service; (3) the name of the party charged; (4) the designation of the party to whom the services were rendered; (5) the services in detail, and the charge therefor, together with the costs of apparatus, etc. In order to prove the claim in the Orphans' Court, all these requisites must appear on the face of the book, as this being a proceeding in which the other party is dead the claimant is not a competent witness. In a proceeding in the Common Pleas against a living debtor, the physician would be allowed to testify in his own behalf, and in that instance might be permitted to use a book which, by reason of being made in hieroglyphic characters, could not be offered in evidence, as a memorandum to refresh his memory, provided the said memorandum was made at or about the time the services were rendered; but the books should always be kept in such a manner that they will possess all the requisites of books of original entry and be admissible to any court having jurisdiction in these matters.

Dr. J. Thompson Schell referred to the case of a physician who had died with a considerable amount of money owing him, but by reason of the fact that nobody could understand his bookkeeping his widow was able to collect but very little thereof. He recommended that the books be kept in such a manner that anyone could understand them, and felt that every man owed it to those dependent upon him to do so, as accidents are so liable to occur.

Dr. William H. Good referred to the class of patients who after paying a physician one or two visits and running up a bill go elsewhere, many times in addition boasting that they do not intend to pay the Doctor's bill, one of this character having recently come under his care.

Value of Organization.—Dr. Frank C. Hammond referred to the practice in Augusta, in which city the profession is thoroughly organized, where each physician has in his office a large printed card stating the fee for each office visit, each house visit, each of the various operations, etc., below which price no physician will take a case. He considered that this consistently demonstrated the value of organization of the medical profession.

Rid to Community of Illegal Practitioners.—Dr. Henry Beates, Jr., referred to the fact that the courts would fix the fees of a physician at such an amount as has been decreed by custom. He urged the necessity for the protection of the regular physicians by statutory enactments calculated to rid the community of illegal practitioners. He also remarked the fact of the attack upon the constitutionality of the legislation providing for medical State board examinations as a prerequisite to the permitting of physicians to practice, citing from the opinions of eminent jurists who had sustained it. He believed that the profession should receive more and higher recognition, which could best be attained by protective legislation and the eradication of the irregular practitioners.

BOOK REVIEWS.

Materia Medica, Pharmacology and Therapeutics: Inorganic Substances. By Charles D. F. Phillips. Third Edition. Longmans, Green & Company, New York, London and Bombay.

It is now twenty years since the first edition of Phillips' Materia Medica was projected, and ten years since the second edition appeared. During this time an immense advance has been made along the lines of pharmacological research, and we are pleased to note that in this third edition the author has kept abreast of this new advance, and practically rewritten his Pharmacology, as this third edition is an almost entirely new work. Most of the sections have been revised and rewritten and a full discussion has been accorded a number of the new remedial agents.

We feel that the factor which is of particular value in this work is the rich therapeutic experience of the author and the full therapeutic discussions which have been incorporated in it. These far outreach the discussions on pharmacology proper, and are so arranged as to make, we believe, a very useful and practical work on general therapeutics.

The captious might be inclined to believe that a little too much attention has been given in the therapeutics to a haphazard gathering of individual experiences from the medical journals, but when it is borne in mind that the author has digested these experiences of others and incorporated them with his own, this criticism seems of little weight.

The work is extremely suggestive, even though at times the pharmacological discussions fall below the level of modern research. It can be recommended as a practical and useful volume, particularly for practitioners.

Pain and Its Indications. By Dr. E. E. Hill. G. P. Engelhard, Chicago.

Dr. Hill's Manual contains many valuable suggestions for the treatment of pain. It is much more, however, than merely a compend of remedies that can be used to alleviate pain. Pain, while one of the most important symptoms of disease, is also a true conservative process since it points to the necessity for the removal of some pathological condition to which it is due, rather than merely the deadening of discomfort by anodyne drugs. Dr. Hill has, we think, avoided the Scylla of merely symptomatic treatment of pain without falling into the Charybdis of writing a complete textbook of all the ills accompanied by pain to which flesh is heir. As it is, however, we doubt whether the book will not prove a source of some unthinking medication by those who will not recognize its diagnostic as well as therapeutic helpfulness.

A Practical Treatise on Medical Diagnosis. By Dr. J. H. Musser. Fifth Edition. Revised. Lea Brothers & Company, New York and Philadelphia.

It is undoubtedly one of the most encouraging signs in present-day medicine here in America that there should be so much demand for books on diagnosis. It is not so long since the great cry was for books on treatment. There has come a very general realization, however, that treatment must mean very little unless the exact nature of the disease from which the patient is suffering be diagnosticated. It is especially encouraging, then, to find that so excellent a volume as Prof. Musser has provided, so thoroughly scientific and complete, has received the attention it deserves and goes so rapidly into its fifth edition.

The present edition has been increased considerably in size and yet there is not a single thing in its pages that is superfluous. Indeed, in spite of its apparent length there is much evidence of judicious condensation. None of the most modern suggestions have been omitted. In this respect indeed the work is very full and contains a number of excellent tables sure to be helpful to the busy physician.

A System of Practical Surgery. By Prof. E. von Bergmann, of Berlin, Prof. E. von Brüns, of Tübingen, and Prof. J. von Mikulicz, of Breslau. Volume 2, translated and edited by Prof. William T. Bull and S. C. P. Flint. Lea Brothers & Company, New York and Philadelphia.

The second volume of this system has just appeared. It is a worthy companion of the first, and all that we have had occasion to say in commenting on the first volume, regarding the general character of the work, its scope, its completeness, we can thoroughly endorse in our review of the second volume.

The present volume deals more particularly with the surgery of the neck, thorax and spinal column. Malformations, injuries and diseases, in their respective aspects, are very thoroughly considered in twenty-six chapters. Nothing is left out that we can find, every possible condition and complication of a surgical nature that has ever been described is here considered in a sound, practical and thoroughgoing manner.

In one regard we note a distinct advance over the first volume, in the large amount of illustrations in the present text. It may be that the subject has lent itself more readily to illustration; at all events, the value of the volume to the practitioner is vastly enhanced by the rich store of well selected and useful illustrations.

The work is too large to consider in detail, so that we can practically only repeat our expression of opinion that up to the present time no work of the same class has appeared in English. The completed system promises to be a classic for all time.

Adolescence, Its Psychology and Its Relations to Physiology, Anthropology, Sociology, Sex, Crime, Religion and Education. By G. Stanley Hall, Ph.D., LL.D., President of Clark University and Professor of Psychology and Pedagogy. In Two Volumes. D. Appleton & Company, New York.

To faithfully mirror within the narrow confines of a book review some of the important features of these volumes of Dr. Hall's is beyond the ability of the present writer. He can only state his impressions, believing the work one of such transcendent value as to leave the mere words of acclaim a shadowy mockery of the real thing.

No work of such a serious and thorough character bearing on the growing human being is known to us. It is, we believe, destined to be a classic for all times and a work that should be made a part of every man's liberal education.

To the physician who understands and correctly estimates his large opportunities as a guide to the father and mother in the healthy development of the family, Dr. Hall's work makes a special appeal. The scientific language, at times overpowering in its technicalities, is no bar to the general practitioner's understanding, and from its many pages much inspiration and practical concepts may be gathered.

We believe this an invaluable work—the result of many years of hard work by one of America's most brilliant teachers—and one deserving, if not demanding, a place in the library of every physician of intelligence and cultured aspirations in this country.

Progressive Medicine. Edited by Dr. Hobart Amory Hare. Volume 2, June, 1904. Lea Brothers & Company, New York and Philadelphia.

The second number of the new series of Progressive Medicine follows the pattern of its June predecessors in taking up the Surgery of the Abdomen, including Hernia, by W. B. Coley; Gynecology, by John G. Clark; Diseases of the Blood and of Metabolism, by Alfred Stengel, and Ophthalmology, by Edward Jackson.

The marked reduction in price of this quarterly places it within the power of every practitioner to really keep abreast of the times, and one need never be in the "back woods" with this incomparable series of digests before one; for these are not mere abstracts, or clippings, pasted on sheets and thrown together on a page by the printer's art, but carefully worked over, compared and critically selected contributions which reflect the distinct "Fortschritte" made in medical science and the practitioners' art.

Graves' Disease with and Without Exophthalmic Goiter. By William Hanna Thomson, M.D., LL.D., Physician to the Roosevelt Hospital, New York, formerly Professor of the Practice of Medicine, New York University Medical College. William Wood & Company, New York.

Dr. Thomson's purpose in this monograph is to emphasize the fact that the symptoms of Graves' disease are by no means necessarily connected with any disturbance of the thyroid gland, or of its accessories. He gives a series of clinical histories of 28 patients, in whom there was no evidence of any involvement of the thyroid, and compares their cases symptom by symptom with the clinical histories of 42 patients who had the usual goiter seen in what is called exophthalmic goiter. Dr. Thomson succeeds in making out a very good case for his theory. There are many physicians now who consider that certain latent forms of Graves' disease may exist without any symptomatic involvement of the thyroid. The evidence may not yet be a demonstration, but it is very nearly so. There is no doubt that these clinical studies will be of value for those interested in Graves' disease and cognate affections.

A Manual of Fever Nursing. By Reynold Webb Wilcox, M.A., M.D., LL.D., Professor of Medicine in the New York Post-Graduate Medical School and Hospital. P. Blakiston's Son & Co., Philadelphia.

Dr. Wilcox's monograph on the treatment of fever has a very interesting subject. The manual includes chapters on all the forms of fever, the continued and intermittent types, as well as the exanthematous and also the thermic form, with its phases of heat exhaustion and insolation, which are of such special interest at the present season of the year. The book generally is of rather theoretically conventional character with the air of being a compilation instead of an expression of results gained from actual practice. There is not as much in it as in most text-books of medicine with regard to these special subjects, so that we find it difficult to understand just what place the monograph is meant to take for the student and practising physician.

International Clinics, a Quarterly of Illustrative Clinical Lectures and Specially Prepared Clinical Articles on Treatment, Medicine, Surgery, etc. By Leading Members of the Medical Profession Throughout the World. Vol. I., Fourteenth series. J. B. Lippincott Company, Philadelphia.

The present volume of the International Clinics contains some excellent practical and suggestive articles. The first article in the volume, "The Chloride Reduction Treatment of Parenchymatous Nephritis, by Widal and Javal," is especially likely to attract attention. The subject is very well stated in the second sentence—"With four arteriosclerotic patients suffering from interstitial nephritis, the daily absorption of ten grams of sodium chloride was found to produce neither edema nor any other disorder. Whereas, with two patients out of three suffering from parenchymatous nephritis, this dose gave rise to extensive edema." The conclusion of the study is that the nature of a food is less important in nephritis than its content of salt.

Other interesting articles in this volume are on the therapeutic applications of colloid silver, by Drs. Netter and Salomon, physicians to the Paris hospitals, and two articles on the non-operative treatment of various pathological conditions of the genital tract in women. An especially interesting article is that by Dr. Pritchard, of New York, on peripheral neuritis. In general it may be said, however, that too much space is given to an excellent but after all conventional review of the recent literature—a feature which every medical journal seems to consider it advisable to emphasize just now. Old subscribers to the Clinics used to rejoice in the fact that it was different from the others.

What we owe to Experiments on Animals. By Stephen Paget. The Scientific Press, Ltd. The Case Against Antivivisection. By Stephen Paget. The Scientific Press, Ltd., London.

These two little volumes which the writer calls pamphlets are really condensations of longer articles. They contain in brief all that it is necessary to know in order to convince any doubter of how much has been accomplished for medicine by experiments on animals and how much harm therefore would likely result if the anti-vivisectionists were to succeed in their program of the limitation of animal experiments. Not infrequently it happens that physicians wish to know where they can obtain in condensed form just such information when for some reason in their towns the anti-vivisection crusade becomes more active than usual. Nothing that we have ever seen so completely fulfills this purpose as these two little volumes. Here there is ample material for demonstration provided, of course, they are approached with good will.

ORIGINAL ARTICLES.

REPORT OF A CASE OF RUPTURED ECTOPIC GESTATION.[1]

BY JOHN W. COE, M.D.,
OF NEW YORK.

THIS case is reported somewhat in detail, not because of the rarity of the condition, but on account of the difficulty presented in diagnosis:

C. T. C., aged twenty-nine years, married nine years; family history negative; habits excellent.

Previous History.—Eight years ago patient was suddenly seized with an attack of pain, general over lower abdomen. This was so severe that a hypodermic of morphine was necessary. A good recovery followed. The patient, at that time, lived in another city and the attending physicians made the probable diagnoses of gravel. Two years later there was a similar but more severe attack, the pain persisting for about two days. This also required morphine. The diagnosis of gravel was again made, some small particles being recovered by the physician. Since that time the patient has been very well. There has never been any evidence of an anemia.

Menstrual History.—Patient has always been regular except that preceding the two attacks of gravel there was some slight disturbance of this function. The last regular period before the present sickness began on November 29, 1903. One week later, on December 6, there was a slight flow for one day. At this time the patient felt perfectly well.

Present Illness.—Patient was aroused in the middle of the night of December 11 by a pain over the lower abdomen. This disappeared after urination, but was followed by a marked chill of about two minutes' duration. By morning all symptoms had disappeared and the patient decided that she had again passed gravel. No physician was called. She was then around, as usual, until the afternoon of December 18, when she was suddenly seized with a sharp pain over the lower abdomen, not at all localized. This was accompanied by nausea, vomiting and marked weakness.

Physical Examination and Course of the Disease.—The patient was first seen about three hours after the onset of the attack. At that time all acute symptoms had subsided. There was no tenderness or rigidity. Temperature and pulse were normal. The case was then considered one of gravel and plenty of water with bicarbonate of soda ordered. The next morning the patient was seen by one of the best known consulting physicians in the city, who agreed with the above diagnosis.

Examination of the urine was as follows: Clear, amber, acid, acidity of 10 c.c. urine = 10.8 c.c. n-10 NaOH (Normal being 2-4 c.c. of n-10 NaOH); Sp. gr., 1.040; albumin absent; glucose absent. Urea, 2.4 per cent., uric acid 0.163 per cent. Microscopically, no casts or crystals were found, but red blood cells were fairly numerous. The patient remained in bed during that day and night and was in excellent condition. The next morning, December 20, while still in bed, she suddenly felt very weak and fainted several times. There was some nausea and a dull, heavy pain was complained of in the right lower abdomen. Urination was accompanied by a sharp pain. At the time of the examination by two physicians a little later there was a decided change in the condition. Pallor was marked and patient could scarcely be roused enough to answer questions. The pulse was feeble, from 115 to 120. On palpation slight tenderness was complained of over right side of abdomen and this could be traced up toward the kidney of that side. Vaginal examination elicited no tenderness or evidence of any hemorrhage. A ruptured pregnancy was thought of but the previous history with the urinary condition and absence of anything by vagina made us think that we were dealing with a calculus somewhere in the urinary tract and that this had ruptured through giving a profuse hemorrhage.

Blood examination on this day showed: Red blood cells, 3,100,000; white blood cells, 21,000, Hb., 55 per cent. Differential count, polynuclears 73.0 per cent.; lymphocytes, 14.8 per cent.; large mononuclears 12.0 per cent. There was a moderate polychromatophilia and slight deformity. The patient soon began to improve under slight stimulation. She was seen that afternoon by another consulting physician and operative procedure was advised against.

The afternoon temperature on this first day was 101.8° F., and the pulse 116, with the general condition improving. During the next three days the temperature varied between 102.8° F. in the evening and 101° F. in the morning, the pulse gradually becoming slower and stronger. The patient was then seen by one of the best-known general surgeons in the city. He would not venture a positive diagnosis, but thought the condition either an unusual form of appendicitis or an extra-uterine pregnancy. As the patient was improving and nothing definite could be made out by abdomen or vagina operation was advised against. During the next two weeks the temperature remained irregular, varying between 102.2° F. in the evening and 100° F. in the morning. The general condition and the blood steadily improved. On December 26, Dr. Wm. M. Polk was

1 Received for publication April 30, 1904.

called in consultation and at once pronounced the case one of ruptured tubal pregnancy. At that time a good-sized mass could be plainly felt on the right side. The patient was kept very quiet and abundant nourishment given preparatory to an operation. The lowest temperature reached during the twenty-four days which elapsed between the apparent rupture of the sac and the day of the operation was 99.4° F. in the morning and 100.2° F. at night, the pulse getting as low as 82.

At the operation on January 10, 1904, a mass the size of a large egg was found in the right broad ligament. In the center of this mass there was a small cavity, the surrounding wall being mostly of clotted blood. The ovary was adherent to this mass. In the pelvis and Douglas culde-sac was considerable old blood, evidently from the original rupture. Nothing was found to lead one to think that the two attacks of so-called gravel of previous years were similar to this illness.

Pathological examination by Dr. J. S. Thacher showed placental tissue and clusters of decidual cells around the small cavity in the center of the mass.

The patient's convalescence was uneventful. Certain points in connection with this case seem to deserve particular notice.

The urinary condition of high specific gravity, high acidity and containing red blood cells, especially with the history of previous attacks of gravel, was misleading. It should be added that specimens of urine examined were not obtained by catheter. Early in the attack, before anything could be made out by the vagina the acute anemia was the only finding which should have made us more strongly suspect a ruptured pregnancy. The red cells and hemoglobin were reduced nearly one-half and with this there was, on the day of the rupture, a leucocytosis of 22,000. Two days later there was marked polychromatophilia and variation in the size and shape of the cells with beginning regeneration as evidenced by the presence of normblasts.

SOME INTERESTING OBSTETRIC EXPERIENCE.[1]

BY J. J. GURNEY WILLIAMS, M.D.,
OF PHILADELPHIA.

In my work among the lower classes I have had the opportunity of seeing quite a number of interesting and difficult labors. I regret that I have not taken the histories in several cases of as much, if not more, interest than those reported in this paper. It must be remembered that three of these women were delivered under the most trying and unhygienic surroundings, without the assistance of trained nurses and amid everything but cleanliness. The woman dirty, the bedding filthy, no clean towels, and hot water procured from a rusty kettle heated over a wood fire. Any of you who have gotten your obstetrical experience in the slum districts will appreciate the difficulties to be overcome. My reasons for presenting these cases is largely a selfish one—the gain to be acquired by your criticisms and discussion.

Case I.—White, aged thirty years, primipara. No history of any previous kidney trouble. I first saw this patient after she had passed her calculated time nine days and was sent for because she believed the membranes had ruptured after some irregular and very weak pains. The history given me was negative up to four weeks previous to my seeing her when her limbs began to swell, with puffiness under the eyes. She passed large quantities of muddy urine with pain and suffered greatly from backache, headache and nervousness.

Patient's skin was dry and waxy, eyes bright and staring, heart weak, rapid, with marked accentuation of second sound, also a loud aortic murmur. The woman started and trembled at the least sound. Feet and ankles were swollen and pitted on pressure, vulva tremendously swollen, so much so that she was compelled to lie with thighs separated. Vaginal examination was difficult on this account; small outlet, os admitted finger to first joint, very rigid and unresisting; vertex presented first position, fetus living. Advised immediate delivery, to which consent was given.

With the assistance of Dr. J. W. Kennedy and a student who administered the anesthetic, manual dilatation was begun. This was found to be a very difficult procedure on account of the rigidity and lack of elasticity of the os. After about twenty minutes it was possible to make a high application of the forceps and traction was started. At this time the student informed us that the radial pulse was absent, her pupils widely dilated and the breathing jerky and hard. She was also sweating profusely. The patient's condition demanded rapid delivery, yet neither Dr. Kennedy nor myself could move the head, the os still being hard, unresisting and thick. I would say here that the strength of arms and shoulders only were used, but the anesthetist was compelled to hold the woman in bed. It was decided on account of the conditions present to incise the os, which was done by scissors, cutting the right side nearly to vaginal junction. Even after this procedure it took all the strength of one accoucheur with pressure above by the other to drag the large head through the cervix. This was accompanied by profuse bleeding and at the same time the forceps began to slip, so that they were taken off and reapplied, and the head quickly delivered.

Following the birth of the head the patient had the most profuse hemorrhage I have ever seen. The hand was quickly introduced into the uterus and placents delivered, the uterine cavity being immediately packed with sterile gauze. While this was being done the anesthetist was administering strychnine, atropine, and morphine hypodermically; one quart of normal salt solution was given by the bowel and hot bottles were placed

[1] Read before the Northwestern Medical Society of Philadelphia, March 1, 1904.

about patient, whose bed was raised at the foot. She was pulseless, had two pronounced convulsions, and was barely breathing, her condition being such that all present expected her to die. There were faint heart sounds, but no respiratory movement in the ten-pound baby, which was plunged into hot water; artificial respiration and direct mouth to mouth inflation begun; this was followed in fifteen minutes by the first respiratory effort. This baby died on the eleventh day from eclamptic convulsions.

I omitted to state that previous to administering the anesthetic, which was ether, I catheterized the patient and found the urine loaded with albumin.

The subsequent history is briefly as follows: No water passed for twenty-four hours, the catheter bringing away eight ounces of muddy fluid containing albumin. Basham's mixture, one-half-ounce t.i.d. with digitalis, gtts. 10, also a saline mixture containing iron. Vomiting was present for twelve hours, but was controlled by hot lime-water. Gauze removed in twenty-four hours, no hemorrhage following. From this time the patient made an uninterrupted recovery, the edema disappeared, urine was free from albumin and bowels moved freely. She was up on the nineteenth day.

I saw this woman ten months after her confinement. She was working hard and looking well and strong. She informed me that she does not have any backache or headache, and does all the cooking and housework without fatigue.

Remarks on Case I.—It must be remembered that I did not see this case until after the membranes had ruptured, therefore no time was allowed me for preparatory treatment. Chloroform, under the circumstances, both as to her heart lesion and the lack of experience of the anesthetist, would probably have killed the patient. That I was justified in cutting the cervix, was manifest in that more harm would have resulted had the head been dragged through by forceps; in fact, I believe this was not possible. That the free hemorrhage, normal salt solution and morphine probably saved the woman.

Case II.—Past history not obtained, other than that the patient had had seven labors, all hard, two demanding forceps, three babies being born dead. I was called to see this case after she had been in hard labor for thirty-six hours. The student informed me that there had been no progress for fourteen hours. My examination was difficult on account of large varicose veins of vulva and thighs, an extensive laceration of the perineum, which was the cause of the large recto and cystoceles, the bladder during each pain protruding through the vagina. The os was about the size of a quarter, rigid and unresisting; vertex presenting.

As this patient was having strong pains and as she did not want forceps used, I advised morphine sulph. gr. ⅛, atropine gr. 1/100 and quinine gr. 30. This was at nine in the morning. At four o'clock patient was considerably weaker, as were also the pains. Ether was administered and manual dilatation begun. In twenty minutes an effort was made to apply Simpson forceps, but the blades being too short a modified Hodge forceps was substituted. The head was engaged and brought well down and the cervix was dilating nicely when suddenly, from what cause I cannot say, the head slipped from the blades and at once receded, following which an examination showed an arm prolapsed into vagina. With considerable difficulty this was returned, podalic version undertaken and what was taken to be both feet secured. At this time it was found that the arm had again prolapsed. This had been mistaken for a leg, and was again returned. The thigh already in the canal so blocked the cervix that it also was pushed upward and both feet secured. The child, dead, weight 10½ pounds, was quickly delivered, followed by considerable hemorrhage. Normal salt solution, one quart, by enema; ergot one dram and strychnine, gr. 1/20 hypodermically were given. This patient made a speedy recovery, getting up on the twenty-first day.

I feel that should a similar case come under my care that I would undertake to deliver so soon as possible, as it must be remembered that this patient was allowed to increase her exhaustion from 9 A.M. to 4 P.M. There were no signs of fetal life on my first examination, therefore the mother's safety and comfort had only to be considered. Axis traction forceps would possibly have given quicker results, yet no delay was encounterd when once the forceps was applied, excepting the slipping of the head from the blades.

Case III.—Primipara, aged twenty-seven years, of strong build. Was called after she had been in labor twenty hours. She was up and about the room, having pains at intervals of about thirty minutes, lasting one to two minutes.

Examination.—Os dilated to size of a quarter, membranes intact, during a pain a foot could be felt, as could also the umbilical cord; the head was high up in the right flank. Abdomen flat, head felt on right, fetal heart sounds present, but feeble. Membranes were ruptured with finger during a pain. Ether administered and manual dilatation with podalic version performed without much difficulty, the head moving upward when the membranes were ruptured. I want to say here that I attempted external version without success, the head rising each time it was brought to present. The feet were secured and at once the cord prolapsed into the palm of my hand. I was unable to replace it, so quickly delivered by Mauriceau's maneuver. Child living, weight 8½ pounds.

The most interesting point in regard to this case was the finding of a fibroid about the size of a large lemon on right side of fundus. Whether it was because of this I am unable to say, but the uterus would not contract for several minutes following delivery of placenta, at the same time there was very little hemorrhage. Patient up and about on the sixteenth day.

Remarks on Case III.—This patient for five days showed symptoms of septic infection. Tem-

perature 100° to 103° F. Pulse up to 120 and a foul-smelling lochia; coated tongue, headache and chilly sensations. She received quinine gr. 8 daily, with milk punches and strychnine gr. 1-40 t.i.d. There was no perineal tear which could be seen or felt.

Case IV.—Primipara, aged thirty years, colored, of slight build. Requested to see this patient by Dr. C. H. Weber, who had been sent for on account of membranes having ruptured several hours previously. He diagnosed an arm presentation. The patient had not had any pain and informed me that she was sure the baby was dead, as heartburn had troubled her for thirty-six hours, also no movement had been felt for this time.

Examination.—Spacious vagina, head to left, no fetal heart sounds heard. Membranes ruptured, elbow presenting, head in left flank, uterus high in pelvis. Ether administered, manual dilatation and version attempted, which was very easily accomplished, but, unfortunately, with occiput posterior. I now made a high application with the Simpson forceps and procured good engagement of head. With considerable force the head, also the cervix, were brought to the vulva. I now advised taking forceps off and allowing the woman the opportunity of delivering herself, with the hope that the head would rotate anteriorly. Ether was withdrawn, quinine grs. 10 in capsule to be taken with a cup of very hot strong tea, this to be repeated in one-half hour. I saw this patient again in three hours and found her in much the same condition, with the exception that she was having good, strong pains at intervals of about five minutes. Here I would like to call your attention to a point of interest. I made an examination at 6 P. M. and found the os size of half-dollar, this was during a pain, head in same position, but cervix softer and not so inelastic. In forty minutes from this time, in answer to my question "Could she feel the head progressing?" she answered in the affirmative, the examination showing the head on the perineum. Patient turned on left side and in the next two pains head was born with occiput posterior, which was at once followed by a discharge of foul-smelling gas, without any perineal tear that could be seen or felt. The baby, weighing about nine pounds, was dead. I worked thirty-five minutes over this child without results. This patient never had a temperature over 99° F., nor pulse above 80.

Remarks on Case IV.—This was a very interesting case to me, as I was in doubt as to the advisability of not interfering at all, also as to applying forceps. My reasons for applying forceps were as follows: (1) These cases when left alone usually require some aid from our hands to complete delivery; (2) the confidence that I could engage head with forceps and deliver if necessary with slight laceration; (3) that, should spontaneous version occur, I would still have to aid in the delivery, as in premature rupture of the membranes, a faulty position rarely turns to a normal position; (4) the fetus being dead there was less likelihood of spontaneous version occurring; (5) should there be active pains, even for a short time, I am nearly convinced that a transverse presentation should not be allowed to wait in the hope of spontaneous version taking place.

I would call your attention to the statistics of Merz, as quoted by Williams, of 160 cases of rupture of the uterus. Twenty-six, or 16¼ per cent., resulted from neglected transverse positions. This alone would cause us much anxiety in waiting. Again, in these positions we find the pains are of a tetanic type, which, I believe, is the explanation of rupture in some cases. My reasons for doubting the advisability of not interfering are the following: (1) That the vertex would probably rotate anteriorily better than it could rotate with forceps; (2) that I was almost certain that the baby was dead and, therefore, felt there was less chance of the pelvic floor being injured by the woman's delivering herself; (3) that the patient would have less opportunity of acquiring any septic condition by non-interference; (4) that there was every reason to suppose she would deliver herself, having had no pains previous to my seeing her.

Case V.—White, age thirty-one years, of slight build; normal weight about 95 pounds. Patient married twelve years, six weeks following marriage pregnancy was interrupted by jolting of a Broad Street bus, recovery prompt and uneventful. Five years following became pregnant again, accompanied by severe and persistent nausea and vomiting, which was not controlled or lessened by drugs. Exhaustion, loss of weight and prostration, with inability to retain nourishment by mouth or bowl, were deemed sufficient cause for the induction of a therapeutic abortion. Following the introduction of a catheter the patient aborted, but was many weeks in regaining her strength.

Since that time she has been in fairly good health. In January, 1901, she suffered from an impaction of the bowels requiring manual removal under ether. She was in good condition until January, 1902, when she had missed one period three weeks. Nausea and vomiting appeared, the patient being unable to retain anything liquid or solid, even when the stomach was empty; mucus and bile would be ejected and retching was almost continuous. Starvation was tried without success, bowel feeding was likewise a failure, partly on account of a very sensitive and painful rectum and partly because of lack of cooperation of the patient herself, as this had been tried during her former pregnancy without success. Cocaine, camphor, carbolic acid, champagne, iced brandy, black coffee, bromides and morphine all failed, individually and in various combinations, not only to control the vomiting or nausea, but to be retained more than a few minutes. The patient was rapidly prostrated, extremely emaciated and completely exhausted. A consultation was called and a therapeutic abortion advised. This was after I had treated patient for two weeks without success, a further consultation was called

and waiting four days, with starvation and applications of silver nitrate, solid stick, to cervix was advised. This was tried without the slightest benefit, the woman becoming weaker and complaining of intense headache.

At this time, three weeks after vomiting first appeared and six weeks following conception, it was decided by all that a therapeutic abortion was necessary to save the patient. Against my opinion a No. 7 silk catheter was introduced with considerable difficulty. At the end of six hours it slipped from the uterine cavity and was again introduced, accompanied by slight bleeding. In twenty-four hours, there being no signs of uterine contraction, it was removed and a dilation and curettement advised. This I did on the following day, dilating one inch, the finger and curette bringing away about three drams of membrane and fetal structure. Douching of uterine cavity followed by iodine and a light gauze drain to fundus and later by a copious rectal injection of normal salt solution. Gauze was removed in twenty-four hours. Nausea and vomiting ceased the following day, patient was able to retain liquid nourishment and slept well. From this time she made a very satisfactory but slow recovery.

Case VI.—For the following notes I am indebted to Dr. J. C. Gittings, who asked me to see this case with him. White, age thirty years. Father died of paresis. Mother and sister well. No serious illness in the past. Engaged to be married six years. Not altogether happy, had been nervous and subject to crying spells of late. Married in October, 1902, and dreaded the idea of pregnancy. (My first question to the husband was "Does your wife want a baby?" He told me she was almost as anxious to have an heir as was he.) Last menstruation June 6, 1903. Early in August first noticed nausea, and vomiting began on August 10. In bed continuously from that date. No food of any description retained, ingluvin, cocaine, bismuth, chloral, chloretone, bromides and opium tried without success. In ten days vomiting ceased, but was succeeded by intense retching. Two days following mild delirium was noticed, pulse 100, wiry, took a very little nourishment, retching persistent. Constant retching all night; much weaker; pulse 140, temperature 101° F.

I saw the patient at this time and found her moaning and tossing, cheeks flushed, eyes staring, pulse about 150, temperature 102° F. She did not recognize anyone, was greatly emaciated and when roused would complain of pain wherever she was touched. Retching was present, with ejection of bile-stained mucus, her breath had an intensely acid odor. Pelvic examination showed a pregnancy of about ten weeks' duration; uterus in front, freely movable, os closed. Therapeutic abortion was advised. This I did without an anesthetic, but the pain caused by this procedure compelled me to stop after breaking up the membranes, and introducing a gauze drain. I felt that should uterine pains take place the woman would empty the uterus. Dr. Gittings called me in forty-eight hours, as there had been no uterine pain, but the retching had subsided, patient taking some nourishment, mental confusion and delirium unimproved. I advised emptying uterus under ether. This was done at 9 P.M., patient standing operation well. The whole uterine cavity was carefully explored with the finger and all substance removed, followed by a normal salt solution douche to fundus, and a light gauze drain. Temperature following operation, 99° F.; pulse 130.

Further Notes By Dr. Gittings.—Patient stronger, dementia more active, sleeps very little, takes some nourishment; recognizes her family. Three days following operation Dr. Burr diagnosed acute dementia, patient takes nourishment only at times, sleeps fairly well, temperature 98° F., pulse 114; mind more clouded, talks constantly except when asleep, articulation mumbling and indistinct. Uterine condition negative. Eleterium and magnesia produced free catharsis. On the eleventh day some abdominal distention noticed, constant moaning, temperature 101° F., pulse 120. In forty-eight hours from this time the patient died. Autopsy made twelve hours after death revealed marked distention of large and small intestine and stomach. Post-mortem changes advanced. Intensely foul intestinal contents, spleen friable but not enlarged, moderate parenchymatous nephritis. Uterus slightly subinvoluted but mucosa clean, no septic foci, adnexa normal. Diagnosis of death, auto-intoxication.

Dr. Gittings tells me he took charge of this case on August 24, after the patient had been ill twenty-two days.

On looking back over these few cases I have no doubt that there is much to criticize. The real points of interest and of practical value are, By what treatment or procedures, other than those used, could I have obtained better results? Cases like these are continually confronting us, and we are called in late when labor has progressed beyond the time for prophylactic measures and we are compelled to do the best that can be done at this time. Personally I have been literally thrown upon the labors occurring among the lower classes, where there is little choice as to refinement in technic—all procedures being confronted with bad-smelling, filthy and almost unlivable surroundings. I grant that this has little to do with the proper procedures which should be carried out, and it is with the wish of being criticized that I present the cases to you this evening.

Vaccine Virus in Massachusetts.—An inspection of the State's new plant for the manufacture of vaccine virus was among the events of the current quarterly meeting of the Massachusetts Association of Local Boards of Health. A forenoon was spent by many of the members at this model plant at the Bussey Institution, Forest Hills. At the new brick building, which was constructed by Harvard University and leased to the State, the work of preparing vaccine and antitoxin is carried on under the most careful supervision and with the best of modern facilities.

CHRONIC MASTITIS AND DIFFUSE FIBRO-ADENOMA OF THE BREAST.[1] [2]

BY B. FARQUHAR CURTIS, M.D.,
OF NEW YORK;
PROFESSOR OF PRINCIPLES OF SURGERY, UNIVERSITY AND BELLEVUE HOSPITAL MEDICAL COLLEGE, NEW YORK; SURGEON TO ST. LUKE'S AND BELLEVUE HOSPITALS, ETC.;
AND
FRANCIS C. WOOD, M.D.,
OF NEW YORK;
PATHOLOGIST TO ST. LUKE'S HOSPITAL; INSTRUCTOR IN CLINICAL PATHOLOGY, COLUMBIA UNIVERSITY, NEW YORK.

Encapsulated or localized fibro-adenomata of the breast are not uncommon, usually occurring in early life, forming small, movable, slowly growing tumors which are easily cured by extirpation. They appear to have little or no tendency to malignant changes.

A chronic induration of the breast with some enlargement, in whole or in part, is very commonly observed in women in middle life. It is sometimes seen early, even in the third decade, but rarely begins after the menopause, although it may then persist if already present.

We can recognize two pathological varieties in these changes: (1) chronic interstitial mastitis, and (2), diffuse fibro-adenoma. The typical cases of each are easily distinguishable, but the two conditions may appear in different parts of the same breast, and in some cases it may be impossible to determine whether the process found is an inflammation or a new growth. Both may closely simulate carcinoma in their clinical and physical characteristics, so that a diagnosis may be difficult. Both of them also seem to be very liable to carcinomatous degeneration, or to be followed by the development of carcinoma. Inasmuch as only a careful microscopical examination can distinguish between breasts affected by these two changes, the diagnosis between them before removal is impossible. Nor is it very important, the main necessity being to determine that actual changes sufficient to require radical treatment have taken place.

The clinical picture is as follows: In a woman in middle life (whether single or married, childless or multiparous, appears to be of no consequence) an induration takes place in one or both breasts, involving the entire gland, or forming a distinct nodule in one portion. We rarely find the rest of the breast perfectly soft and healthy, even if the superficial examination reveals only one definite nodule. It is seldom that the patient has suffered from any injury or abscess formation which might be considered a cause of the changes. When the process is localized or limited to one lobule, a more or less distinct mass is felt, moderately hard, not freely movable in the breast, but rarely attached to the skin or deep fascia. If a cyst of any size be present the mass is usually elastic, but it is often hard and sometimes of stony hardness like carcinoma. Fluctuation can seldom be demonstrated, the tension and fluid pressure within the walls of the cyst being so great. Small cysts feel like shot or beans embedded in the tissues of the breast; and the larger ones, surrounded as they often are by thick indurated walls, may exactly resemble a small carcinomatous nodule. Usually a nodular or granular induration can be felt in the rest of the breast by careful examination (pressing the gland gently against the chest while palpating with the fingers, especially at the margins), even when the patient complains only of the more evident portion or prominent tumor.

When the disease has advanced equally in all parts of the breast the entire organ feels indurated, uneven on its surface, and when grasped between the fingers gives the impression of being made up of numerous nodules. In a certain number of cases there may be some adhesion of the skin and even retraction of the nipple, in spite of the denial of Bryant and other authorities that adhesion of the skin and retraction of the nipple are ever felt except when carcinoma is present. A retraction of the nipple which is evident before operation occasionally disappears in the breast after removal, probably because of the loosening of the fibrous stroma which had drawn upon the nipple. The axillary glands are sometimes enlarged from inflammatory reaction, and they may be tender to pressure; but they are not so hard as is sometimes the case in carcinoma. As illustrating adhesion of the skin and retraction of the nipple we quote two cases from several which we have seen.

Case I.—M. B., widow; seventy-one years of age. Had noticed a lump in the breast eight months previously. No history of injury, etc. In the internal half of the breast was a smooth cyst the size of a walnut, movable in the tissues. A second mass lay near the nipple which was retracted, and the skin was slightly adherent over this mass. Very little induration was present in the breast. The breast, axillary contents, and pectoral fascia were removed at St. Luke's Hospital, October 10, 1899, and the patient has remained well since then. The microscopical examination showed a typical diffuse fibro-adenoma with cysts.

Case II.—M. W. P., sixty-five years old. Her mother had cancer of the breast. Patient has never been strong; she has borne one child. Three years ago she noticed a small swelling in the right breast the size of a hickory nut, which has been growing slowly until three months ago, when it began to grow more rapidly. Moderate pain in the breast. Patient has lost flesh and strength during the past year. In the superior external quadrant of the right breast is an irregular, hard, insensitive mass with nodular surface, the size of a hen's egg. It is movable on the deeper parts, but the skin is adherent and the nipple retracted. No glands can be felt in the axilla and the arm is not swollen. The tumor was supposed to be carcinoma, and on September 11, 1902, at St. Luke's Hospital, the breast, the subjacent sternal part of

1 This paper was read before the Medical Society of the State of New York, at its meeting in New York, October, 1901, but was not published because it was thought wise to accumulate further clinical evidence of the views presented. This has been obtained and the paper is published with no important changes in the text.

2 Received for publication, April 5, 1904.

the pectoralis major muscle and the axillary contents were removed. After removal the mass was found to measure eight cms. in diameter and to be one and one-half cms. thick, and enlarged glands were found in the axillary fat.

Microscopic Examination.—Fibrous tissue very abundant. Few acini are present and these are cystic in places. The lymph-nodes show chronic inflammatory changes. The tumor is a fibro-adenoma.

Cysts which lie very near the surface may stretch the skin, and the dark color so often present in their contents shows as a blue or purple discoloration. I have seen largely dilated veins on the surface of the breast of some cases (and in one case in the axilla) without any perceptible cause for the dilatation.

The patient is as a rule unaware of the changes which are taking place in the breast, unless a prominent single nodule or cyst has developed, for the process is often painless. In some cases, however, there may be discomfort or actual neuralgic pain. A fear of cancer is generally the cause for seeking medical advice, not the actual suffering caused by the tumor.

We have seen a subacute or even an acute infection added to the existing disease, and then there may be a discharge of pus from the nipple, or one of the cysts may suppurate, with the usual symptoms of acute mastitis. Abscess, however, is a rare complication, and the infected cyst generally discharges through the nipple or the infection is overcome by the tissues; resolution and absorption occur, and the cyst returns to its original size or even disappears.

The progress is very slow, often running for years with little change, and the outcome is a matter of dispute. Sometimes cysts of considerable size will spontaneously disappear by absorption of their contents. In only one case have we had the courage to delay operation for this result.

Case III.—M. R., single, had a rather large cystic fibro-adenoma of the left breast, and we removed the breast and axillary contents at St. Luke's Hospital, October 29, 1896. That side remained well, but she returned in June, 1900, with a tumor the size of a small hen's egg at the axillary border of the right breast, round, firm, not adherent. The rest of the breast appeared to be normal except for a very slight induration between the tumor and the nipple. In view of the perfectly limited area involved, the absence of all indications of malignancy, the evidence we had of the nature of the tumor in the other breast, and the opposition of the patient to further operation unless absolutely necessary, she was allowed to wait, being told to report later. In February, 1901, she wrote, "I find the bunch in my breast has nearly disappeared." In spite of the apparently favorable outcome, we confess that we do not even yet feel at ease as to the final result in this case.

Sometimes the whole fibrous and cystic mass undergoes atrophy, but the absorption may be much delayed, just as a fibromyomatous uterus is late in yielding to senile changes. Such cases explain some of the instances of "disappearing tumors" and of spontaneous recovery from supposed cancer. More usually the progress is continuous; and of interest in this connection is the case of M. R., widow, thirty-nine years of age, native of Ireland, who has twice in the last three years had cysts removed from the left breast. The tisues of this breast felt hard and several small nodules could be felt. One year before admission she had noticed a lump in the right breast the size of a hazel nut, which had grown at first slowly, then rapidly, to its present size, about one and one-half inches in diameter. The mass is rounded, freely movable, and the skin not adherent. Small nodules can be felt in the mass. Both nipples are normal. On September 29, 1900, the right breast and axillary contents were removed at St. Luke's Hospital, and the microscopical report was fibro-adenoma with cysts. It is quite probable that the changes in the left side will require (or have already made necessary) a similar operation.

PROGNOSIS.

In estimating the prognosis we must distinguish between the extensive and the limited cases, and also between cases with very advanced changes and those with slight alteration. In the writer's experience the grade of development is more important than its extent. The advanced cases are marked by great induration, sometimes with edges which are quite sharply defined like those of a carcinomatous tumor. A number of cysts may also be present. In such cases we believe the danger of malignant change is great, whether the whole breast is involved or only a part of the gland. When, however, the induration is slight only one or two small cysts being found, and especially if only a part of the breast is involved, there appears to be more chance of resolution and atrophy taking place. The induration varies from a slight thickening of the mammary tissues to a hardness almost equal to that of carcinoma, and constitutes the most reliable sign of the grade of pathological change and of the consequent danger.

Of a considerable number of cases illustrating the relations between these conditions, chronic mastitis and diffuse fibro-adenoma and carcinoma we present the following as of value.

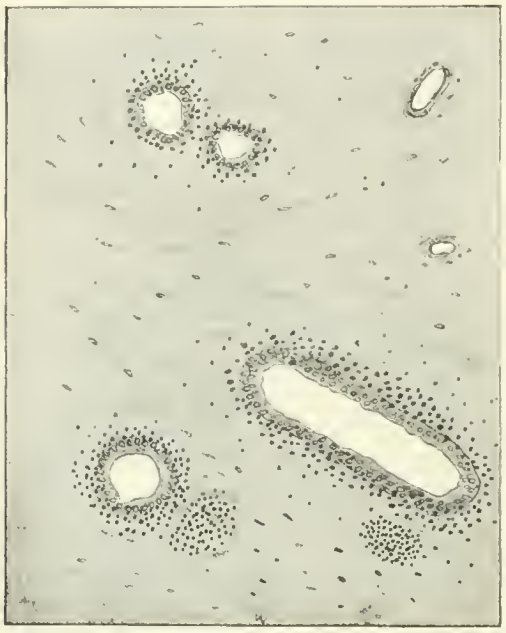
CARCINOMA WITH MASTITIS OR ADENOMA.

The first case was reported by me in the *Medical Record*, June 2, 1888, and the patient's history is so interesting that I repeat it here. Dr. C. N. Dowd showed a sketch of this tumor in a paper on fibrous tumors of the breast in the *Medical Record*, April 16, 1892.

Case IV.—A. W., thirty-nine years of age, English, entered the New York Cancer Hospital. She had been married for eighteen years, had had one child and five miscarriages since, the last one ten years ago. No history of abscess or of injury of the breast. She first noticed the lump

four months before admission, when her attention was attracted to it by a dull, aching pain. It was the size of a bean and grew slowly. For two months she had had pain in the breast and in the arm. The tumor was situated in the upper and outer quadrant of the left breast and consisted of several nodules very sensitive to pressure. There was no retraction of the nipple and no discharge. The most prominent part of the tumor was elastic but without fluctuation. The axillary glands were enlarged but not perceptibly. The other breast felt slightly indurated but there was no distinct tumor in it.

Fig. 1.



Atrophic form with only a small amount of gland tissue and a good deal of round-cell infiltration about the alveoli.—Case M. B.

On March 10, 1888, the breast was removed, also the axillary contents with enlarged glands. Dr. G. C. Freeborn, pathologist to the hospital, reported that the entire breast was composed of dense white tissue, with several cysts from a quarter to one inch in diameter. Microscopically the changes were those of chronic mastitis, but in the neighborhood of the largest cyst was found a nodule of tissue with large granular cells arranged in narrow alveoli and surrounded by a stroma of connective tissue. The lymph-nodes exhibited simple hypertrophy. This patient disappeared until June 19, 1901, when she returned with advanced cancer upon the opposite side. She had had good health in the interval, and the left side was free from tumors, with a healthy scar. At her urgent request the tumor was very thoroughly removed at the General Memorial Hospital, and, as we had expected, by the following March a hopeless recurrence took place in the thorax.

Case V.—B. N., thirty-six years old, admitted to St. Luke's Hospital, June 4, 1902; native of United States; married but never pregnant. She had accidentally discovered a lump in the breast two weeks before. In the right breast were seven distinct nodules, the two largest lying just below and just above the nipple. The latter was not retracted, but it dimpled when the upper of these two growths was drawn away. The masses were irregular in shape, firm, moving on the deeper parts, and the skin was movable over them. Some portions were harder than others, giving the impression of hard nodules in infiltrated breast tissue. The axillary glands were slightly enlarged and hard.

Fig. 2.

Adenomatous type with the production of secondary cysts. There is a moderate amount of inflammatory infiltration.—Case A. H.

The breast, axillary contents, and entire pectoralis major muscle were removed, a frozen section having demonstrated the dangerous nature of the growth, which we had previously considered benign. After removal the nodule above the nipple measured six by five by four centimeters. It was not attached to the skin or deeper parts. Microscopically it contained irregularly arranged alveoli of large oval cells with a fibrous connective tissue stroma. In the same sections were seen adenomatous acini of normal gland tissue and also some which still showed a lumen but had many layers of cells on a membrana propria. The rest of the breast showed adenomatous changes with considerable round cell infiltration around the acini. The lymph-nodes also showed carcinomatous involvement of the same type as the nodule in the breast. The patient continues well (1904), although the glands removed from the infraclavicular triangle were involved, but there is edema of the arm and hand.

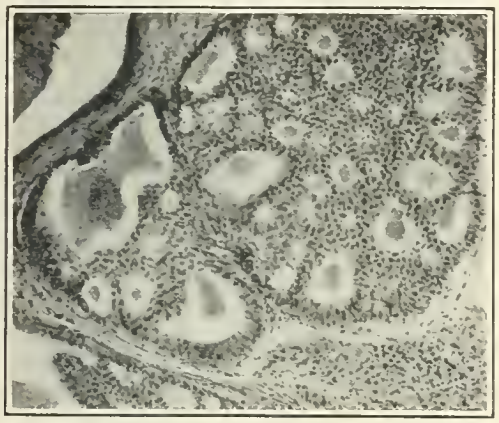
Case VI.—H. M., widow; native of United States, sixty years of age, referred to us by Dr. A. A. Smith, was operated on at her house, October 10, 1902, for a tumor in the right breast, the size of an English walnut, freely movable,

with no adhesion of the skin or retraction of the nipple, and no glands perceptible in the axilla. Examination of the tumor showed a minute nodule of gelatinous carcinoma measuring about twelve millimeters in diameter. The carcinoma was practically limited to this area and could not be found in other portions of the breast, which contained only fibroadenoma. The lymph-nodes were slightly inflamed but contained no metastases. The patient died of apoplexy without known cause, shortly after the operation.

CARCINOMA FOUND ONLY IN LYMPH-NODES.

Case VII.—M. S. R., forty-eight years old; born in United States, married; admitted to the General Memorial Hospital, April 27, 1899. The breast was large, full of hard nodular masses, not adherent. It was removed with the axillary contents and subjacent pectoralis major muscle. Involved glands were found beneath the clavicle. Microscopical examination showed only fibro-adenoma in the breast, while carcinoma was present

Fig. 3.



Highly magnified portion of Fig. 2, to show the formation of secondary cysts in the epithelial masses and also the inflammatory infiltration of adjacent connective tissue.

in the glands. This patient was seen again in September, 1900, with recurrence in the skin about the scar, and with typical central carcinoma of the other breast and involved lymph-nodes on that side.

A similar case, referred to me by Dr. C. E. Quimby, was operated upon at the patient's home, July 25, 1895. No sign of carcinoma could be found in the breast, but the glands were extensively diseased. This patient was alive and well three years after the operation.

WITH CARCINOMA OF OTHER SIDE.

Case VIII.—A. H., fifty-five years of age, married; born in United States; admitted to St. Luke's Hospital, September 9, 1902. Her sister and aunt died of cancer of the breast. Menopause one year before. Had never been pregnant. Had right breast removed five years before for cancer and no further trouble until two months ago, when a mass appeared in right armpit. She had never noticed anything wrong with the left breast and was surprised when shown the tumors there. There was a mass near the scar on the right side, another in the right axilla, and a nodule infiltrating the skin over the right scapula. At the urgent request of the patient these were removed and subsequently when an anesthetic was administered to graft the large area left by the previous operation the left breast was removed also. On the left side the mass was in the internal inferior quadrant of the breast, irregular in shape, very hard and slightly tender on pressure, movable on the deep parts, but the skin over it adherent and the nipple markedly retracted. No glands could be detected in the axilla. The diagnosis of carcinoma was made before operation, but the microscope revealed only fibro-adenoma in the breast, and slight inflammatory changes in the solitary lymph-node which was found enlarged in the axilla.

CARCINOMA APPARENTLY PRECEDED BY MASTITIS OR FIBRO-ADENOMA.

Case IX.—M. J., fifty-two years of age, born in Ireland; married; admitted to General Memorial Hospital, February 3, 1899. She had had for two years a mass in the left breast with occasional attacks of pain, especially at the menstrual period. The mass had increased slowly and was found to be the size of a hen's egg, situated in the lower external quadrant. It was not very hard and was freely movable without attachment to the skin or fascia. The nipples of both breasts were somewhat retracted. Both glands were large and the patient was fleshy. No lymph-nodes were felt in the axilla. The long duration of the tumor and the thickened condition of both breasts made the tumor seem benign, but on removal the microscope demonstrated carcinoma just beginning in a breast the seat of chronic mastitis. The lymph-nodes were normal.

Case X.—M. M., sixty-two years of age; married; native of United States; admitted to the General Memorial Hospital, February 1, 1900; had had an enlargement of the left breast for five years. Examination revealed a tumor in the upper half of the breast, slightly adherent to the skin and pectoral fascia, and some palpable glands in the axilla. After removal the microscope showed adenocarcinoma, not involving the lymph-nodes, apparently secondary to a chronic mastitis.

Case XI.—F. A. G., single, fifty years of age; native of United States; admitted to the General Memorial Hospital, May 4, 1899. Two years previously, after an attack of diphtheria, she had an "ulcer" on the right breast, which remained open for two months. Eight months ago she found a lump, the size of an English walnut, in the same breast just below the nipple, not attached to it. The tumor has now grown three times as large, increasing especially in the last six weeks, and is harder. It is in the center of the breast, the greater part lying internal to the nipple, as large as a small orange, somewhat flattened. The skin is movable over the mass, but

the nipple seems attached and is very slightly retracted. Glands can be felt in the axilla, although the patient is very stout. Adenocarcinoma was found in the breast and also a cyst holding an ounce of bloody serum. The glands were involved. Her physician, Dr. E. J. Thompson, of Hartford, informs me that she "enjoyed good health for two and a half years and then a secondary tumor developed in the crest of the left ileum. Intestinal obstruction caused death without any local recurrence."

Diagnosis.—The diagnosis of these conditions from every lesion except early carcinoma is generally easy, and the purpose of this paper is to show that it is not important to make the distinction between them and carcinoma because they are so frequently followed by the development of cancer that they can be considered practically preliminary stages of that dangerous neoplasm.

Fig. 4.

Drawing to show the combination of the inflammatory and adenomatous types in chronic mastitis.—Case M. R.

The simple congestive thickenings of separate lobes of the breast not infrequently seen during menstruation or associated with inflammatory lesions of the other genital organs, are not so hard to the touch, less distinct in outline, and much more painful to pressure. They are also intermittent and occur in younger individuals.

Retention cysts occasionally found in the breasts are distinguished by their thinner walls, and by the healthy consistency of the remainder of the organ.

The encapsulated fibro-adenomatous tumors, and the intracanalicular fibromata have their own features, such as free mobility, appearance earlier in life and usually occurrence singly in a breast otherwise healthy. The intracanalicular form may have a bloody or serous discharge from the nipple. Cysts may occur with this form, although they are not common. Sometimes the intracanalicular form occurs in breasts which also show the diffuse fibro-adenomatous changes.

The recognition of encapsulated abscesses may present almost insuperable difficulties and may mislead the most careful and experienced surgeon. On this account some authorities urge an exploratory incision in every case of tumor of the breast before removing the organ.

The signs upon which the diagnosis of malignant disease of the breast is to be made are given in the books as follows: Stony hardness of the tumor; its adhesion to the skin or fascia; retraction of the nipple; enlargement of the lymphatic glands; "pig-skin," or "orange-peel" dimpling of the skin; fixation of the breast; ulceration; metastasis and cachexia. But all except the first four signs are so late in development that their appearance indicates that radical cure by operation is impossible.

Enlargement of the lymphatic glands is also a comparatively late symptom; and in some cases it comes so late that to delay operation until its appearance would preclude all chance of a cure. It may also be a very early condition. Again, the lymph-nodes may be invaded by the new growth and yet not be sufficiently large to be palpable. The same uncertainty exists as to the date of appearance of retraction of the nipple and adhesion of the skin, both of them sometimes preceding and sometimes following the lymphatic infection.

The following cases are of interest, as showing how one may be misled by the absence of the usual symptoms of malignancy.

Case XII.—N. M., thirty-seven years of age; married; six children; native of Ireland. Patient had nursed her children and had never had an abscess of the breast. The last child was born fifteen months and weaned only one month before admission. On admission she was four months pregnant. Five months before she had a pain in the right breast and axilla, and soon after found a tumor which she thinks was as large then as now. In the right breast, below, and external to the nipple, was a hard mass the size of an English walnut, freely movable on the deeper parts, and the skin freely movable over it. The nipple was not retracted. A hard gland, the size of an almond, was felt in the axilla. The breast and pectoralis major were removed, with thorough removal of the glands in axilla and under clavicle, at St. Luke's Hospital, August 22, 1899. The following June she was well and had had her child in December. Microscopical examination proved the growth to be carcinoma.

Case XIII.—I. T., single; native of United States; thirty-seven years old. Family history negative. Eight months before admission she had noticed a small, movable lump in the right breast which had grown steadily. Three or four months ago she noticed axillary glands. No pain. A hard, irregular mass about two by three inches was felt in upper outer quadrant of the right breast; nodular on the surface. The skin was adherent; but the mass was not adherent to the fascia; and the nipple was not retracted. Cloudy serum exuded from the nipple on pressure. Several glands could be felt in the axilla. The tumor was removed with breast, pectoral muscle, a very extensive area of skin, and the lymph-nodes, at St. Luke's Hospital, January 19, 1903. The patient (Jan., 1904) is free from local recurrence,

but has paralysis just beginning with signs of tumor in the dorsal spine and an enlarged liver.

Case XIV.—S. P., forty-seven years old; married; native of the United States; admitted to the General Memorial Hospital with a tumor of the left breast near the nipple. The tumor in the lower half of the breast was a tense ovoid, smooth, fluctuating mass, four inches in diameter, not adherent to the fascia and but slightly to the skin. The nipple was retracted, but this was supposed to be due to the tension of the cyst close to it and the tumor was considered benign. It was of ten months' growth. The cyst was found to contain dark-brown fluid and the walls were not very hard. On October 16, 1899, the breast was removed and the axilla exposed by incision, but no enlarged nodes could be felt, therefore no dissection was made. The tumor proved to contain carcinoma. On June 16, 1900, the patient having returned to the hospital with an axillary mass the size of an English walnut, which she first noticed three months previously, the axillary contents were thoroughly removed and found to contain cystic carcinoma exactly like the tumor in the breast.

Case XV.—M. R., thirty-two years old; native of the United States; married; admitted to St. Luke's Hospital, September 4, 1903. She had had seven children, the last born nine months previously and not nursed. Three months before she had accidentally noticed a hard lump in the right breast the size of a marble, which had gradually increased in size and had recently caused pain. One month before admission she had noticed a lump in the right axilla which had enlarged and grown tender. The right breast was pendulous and large, and contained a tense, fluctuating, smooth-walled mass, globular in shape and about two inches in diameter. Near the anterior wall of the axilla was a small mass resembling an enlarged lymph node. The rest of the breast felt healthy. The tumor was not tender to pressure; not attached to the deeper parts or to the skin, and the nipple was not retracted. An exploratory incision opened the cyst and discharged about three ounces of slightly cloudy yellow serum. After evacuation no induration could be felt even with one finger in the cyst and counterpressure outside, the tissues feeling perfectly soft and normal. The interior of the cyst seemed perfectly smooth. A small fragment of the cyst wall was removed for microscopical examination and showed carcinoma. On September 19, the breast and sternal part of the greater pectoral muscle were removed and primary union obtained. Examination of the specimen showed no new growth anywhere in the breast except in the wall of the cyst, which was formed of epithelial cells in a carcinomatous arrangement with little stroma. The axillary fat contained a mass of carcinoma, which gave no sign of having originated in the lmph-node, measuring 3 x 2½ x 2½ cm. Only one node was found and this was not involved.

Many cases of diffuse fibro-adenoma and of chronic mastitis with cyst formation present small densely hard tumors, and it is clear that up to the present there is no absolutely reliable sign to distinguish between these conditions and carcinoma before one of the other cardinal signs of malignancy, such as adhesion of the skin, retraction of the nipple, or involvement of the lymphatics, makes its appearance. We all know too, well the danger of allowing a malignant tumor to remain even a week after its discovery, especially when we consider that the tumor has already attained some bulk and must have been growing for weeks or months before it was detected. It is therefore impossible for the surgeon to wait for the development of these reliable signs and action must be taken at once.

On the other hand, the masses in the breast produced by chronic mastitis and diffuse fibro-adenoma in certain cases present some adhesion of the skin to the surface of the tumor and some retraction of the nipple, so that the simulation of malignant disease may be complete. We must therefore conclude that errors are possible in both directions. Add to this the fact that malignant changes are quite frequent in these indurated breasts, as can be demonstrated by careful microscopical search, while the patch in which the change begins may be so small that it cannot be recognized except by the microscope and may escape careful search by the pathologist, even when he knows that it must be present because he has already found carcinomatous changes in the lymphatic glands.

There is only one legitimate decision for the surgeon to reach in such conditions; namely, that a breast which presents changes so closely simulating the clinical picture of cancer, and possibly containing a small area of carcinomatous change, must be treated like a breast in which an early carcinoma has been demonstrated. The diagnosis between these conditions, and the question as to the probable resolution of these inflammatory changes, or the length of time before carcinoma will develop, are all interesting scientifically; but to test them by awaiting development is playing with human life. The individual patient cannot afford to make that scientific experiment.

Treatment.—The knowledge of these facts must determine our choice of treatment. We can separate these cases into three classes: (1) Moderate induration, limited or general; (2) marked induration, limited to one-quarter of the breast or less; (3) marked induration, general.

First Class.—We need not remove every breast which has a small mass of moderate hardness, or in which the tissues of the entire breast are slightly indurated. A slight induration is very common in women from forty to fifty years of age. These are cases which can be left for time to produce atrophy, the patient meanwhile being kept under regular observation. Nor should we excise every cyst which is of small size, thin-walled and soft, in a normal breast. The cysts can be treated, it is said, by aspiration and pressure, but in my personal experience this method has failed. When-

ever there is indurated tissue in the neighborhood of the cyst or elsewhere in the breast, the accumulation of fluid can be set aside as an unimportant feature of the general disease of the breast tissue. The induration is the real disease, and the case should be treated according to the indications to be discussed below. The determining factor in the treatment of these cases is the degree and the extent of the pathological change as shown by the accompanying induration.

Second Class.—When a small mass is found in the breast showing the characteristic nodular induration, its removal should be urged. Consent should be obtained beforehand for the removal of the entire mamma if the surgeon thinks there is a possibility of discovering positive evidence of malignancy during the operation, or the patient should be made to understand that the operation is preliminary to a careful microscopical examination of the tumor, and that an immediate radical operation may be required if the character of the tumor should be proved by this examination to be dangerous. Banks asserts that the gross appearance of the tumor after section by the surgeon is more reliable than a microscopical examination, but few will agree with him. The writer has frequently made guesses founded upon these appearances and has been wrong as often as right, so that he is unwilling to express an opinion without the assistance of a frozen section which can be made at once before the wound is closed. At the same time it must be remembered that frozen sections are not absolutely reliable and more than once sections have been obtained in our cases from cysto-adenoma and even from a typical encapsulated fibro-adenoma which closely resembled in appearance malignant disease. The thickness of the sections and the indifferent staining account for this uncertainty. This removal of limited masses of the breast must be restricted to tumors involving less than one quadrant of the gland, for if more than this be removed the portion left behind is of no cosmetic or even sentimental advantage to the patient. Some surgeons go so far as to advise the saving of the nipple even when the removal of the entire gland is necessary in non-malignant disease; but the writer's patients appear to be entirely indifferent as to the leaving of some small fragment of the breast,—in fact, most of them have themselves urged the removal of the entire organ as soon as it was made clear to them that a considerable portion must be taken away. Having the nipple does not add to the esthetic appearance and it is dangerous to leave any epithelial structures.

Third Class.—If the induration involves so much of the breast as to leave less than three-quarters of the gland after excision of the diseased portion with a sufficient zone (half an inch to one inch wide) of the surrounding healthy tissues, the entire breast should be removed and the pectoral fascia dissected off with it and the axillary contents removed as well. These latter precautions the writer believes to be wise, for they do not add perceptibly to the risk of the operation when properly performed, and in more than one case, as already mentioned, carcinomatous changes have been found in the glands when none could be discovered in the breast.

While we can lay down these general rules, every case should be carefully studied before deciding upon the method of treatment. Many women particularly dread the terrible malady of cancer and are rendered so nervous by the knowledge that anything exists in the breast in the shape of a tumor, that removal of the organ is the only sure method of restoring their happiness; and we cannot even conscientiously advise waiting, because if the breast already shows pathological changes, no surgeon can honestly assure the patient that carcinoma has not begun. As we remove the suspicious appendix, so should we remove the suspicious breast, even if we feel tolerably certain that dangerous changes have not yet taken place in the suspected organ. The patient has a right to demand this action as a method of life insurance.

THE PATHOLOGICAL ANATOMY OF TUMORS.

BY F. C. WOOD.

The name of "maladie cystique" was given by Reclus to a peculiar chronic condition of the breast, and he also pointed out the fact that the tumors are usually bilateral and closely related to the presence in the breast of a considerable amount of chronic inflammation with the production of dense fibrous tissue. The question was still further investigated by a number of French surgeons, chief among them being Delbet. At first Reclus and others claimed that the development of carcinoma generally followed these changes. The present trend of feeling among this group of observers is that the disease is not progressive, but is self-limited, and that the cysts disappear by absorption of their contents while the glandular areas atrophy. They do not consider that carcinomatous changes are as likely to occur as was once supposed.

In the year 1890, Schimmelbusch collected and described a series of cases of what he called cystadenoma of the breast, and pointed out that carcinomatous changes were to be found in a certain proportion of breasts thus affected. His description has given rise to much discussion as to the exact interpretation of the anatomical findings in these cases, and this discussion has brought to light the fact that there are a number of conditions in the female mamma which are closely related to the change described by Schimmelbusch, and yet possess a distinctly inflammatory character which has been especially emphasized by König.

The growth described by Schimmelbusch forms a tumor arising in the breasts of married or unmarried women, chiefly those who have had no children, and consists of a fibrous tissue growth containing numerous cysts with thick gelatinous contents. The formation of the cysts is antedated by an abundant growth of the epithelium of the acini of the breast tissue, which often fills the

entire lumen of the acinus. This epithelium then degenerates, and the cavity remaining fills with the debris of the cells and with the secretion of the remaining healthy cells. (Fig. 4, a.) The connective tissue does not show any marked inflammatory change and the tumor does not become adherent to the surrounding tissues and it is almost always bilateral. In most cases there is an increase of the interstitial connective tissue, with no definite capsule or boundary to the growth, so that the name diffuse fibroadenoma appears appropriate. In some cases there is an abundant round cell infiltration of the connective tissue, and the adenomatous growth is less marked although cysts are frequent. For these cases we may use the term chronic interstitial mastitis. (Fig. 1.) But there is no sharp distinction to be drawn between the two and one is often in doubt in which group to place certain intermediate varieties of tumor.

The anatomical changes found in these cases may be designated as chronic mastitis or diffuse fibro-adenoma, and are extremely variable, depending upon whether the glandular substance or the connective tissue is the most affected.

The lesions differ distinctly from those found in simple adenoma of the breast and in the special forms of fibroadenoma known as intracanalicular and pericanalicular fibroma, which rarely become carcinomatous and are of interest to the surgeon chiefly because of the physical discomfort which they cause. The breasts show in these cases either a simple increase in the amount of glandular and connective tissue sufficient to form a tumor or a marked increase in the periglandular connective tissue, often accompanied by diffuse mucous degeneration. The masses so formed are as a rule sharply delimited from the remainder of the breast tissue.

The changes which characterize the conditions known as interstitial chronic mastitis or diffuse fibroadenoma are of very different character. The breast may be largely filled by the growth which may contain harder or softer areas, the latter being the cystic portions, or as is more frequently the case there may be many large and small hard nodules scattered through the gland, connected by bands of connective tissue, or the tumor may be confined to a single irregular and ill-defined mass which is but slightly movable. Rarely, however, are there symmetrical oval tumors which are freely movable in the breast substance. These cases are the ones which show the adenomatous type in distinction to the chronic inflammatory. The nipple is occasionally retracted.

Three general types of growths may be observed:

1. Tumors in which the breast has recently been the seat of a subacute inflammation entering the lacteal ducts and involving the periglandular connective tissue. The process is not the same as is seen in acute puerperal mastitis with the formation of abscesses. In chronic mastitis abscesses are rarely developed as the pus, if formed, may discharge through the nipple; the process is rather a low grade inflammation with some necrosis of the periglandular connective tissue, desquamation of the glandular epithelium, and the formation of cysts. These cysts are apparently not formed by the retention of the breast secretion caused by the blocking up of the lacteal ducts; but are due to the inflammation about the glandular structures and inflammatory softening and dilatation, such as can be seen in the early stages of the formation of a bronchiectactic cavity in the lung. The cysts and the dilated ducts are often filled with debris, occasionally with milk and colostrum corpuscles. The general connective tissue of the breast is infiltrated with small collections of leucocytes and the number of connective tissue cells is increased. These are the cases which König has properly designated chronic mastitis, and are illustrated in Case I.

2. The second type of cases are those which are more distinctly of an adenomatous type and are those described by Schimmelbusch and Reclus. Two varieties may be distinguished microscopically,—one in which the glandular acini are filled with masses of cells which have grown out from the walls of the gland; the other, in which the lumen of the acini or the cyst is filled with a papillary outgrowth which simulates an adenoma. The centers of the cell masses may also soften down and form cysts. Cysts may also occur as simple dilatation cavities, having then a lining of flattened epithelium and containing a thin milky or a thin or thick serous fluid of a yellow or brown color, as in case Czarmoniska. The contents may become inspissated and form the so-called butter cysts of the breast. The connective tissue stroma in these tumors varies greatly, even in different portions of the same breast. There may be a large amount of interstitial tissue, either dense in character or soft and infiltrated with a few leucocytes; or there may be very little connective tissue and the tumor may be entirely made up of epithelial structures and cysts. The tumors frequently present a very different appearance in different portions of the growth. One section may show only dense connective tissue with a few normal gland tubules, while a section from another portion of the same breast may be composed mainly of cysts and enormously dilated glands with the lumina filled with cells from the proliferation of the walls. When the gland tubules are actively proliferating, there is as a rule a marked infiltration of the surrounding tissues with leucocytes. Most of the tumors may be included in this category.

3. *Transition Cases with Malignant Changes.*—The breast may contain a small perfectly mobile tumor with all the clinical and gross anatomical appearances of an adenoma; carcinomatous changes may, however, have taken place in some portion of the tumor and invasion of the axillary lymph nodes already begun. Only a minute portion of the tissues may be so involved and the greatest patience is required to find the carcinomatous area which has furnished the cells for the invasion of the lymph-nodes. This is one

of the dangers of relying on the examination of a small section of such a tumor removed for diagnosis, for the remaining portions of the breast in these cases may show the same adenomatous growth in the gland tubules as in those cases in which no carcinoma can be demonstrated.

The morphological distinctions between the adenomatous forms with proliferation of the epithelium of the acini and invasion of the surrounding connective tissue by the cells of the new growth, and the cases in which a true carcinomatous change has taken place, are not always very sharp. It is this fact which led Brissaud to state that the adenomatous type described by Reclus was malignant in its nature, and to draw no distinctions between those cases in which there was simply a proliferation of the epithelium invading the surrounding connective tissue and those in which an actual change to carcinoma had taken place.

The most important point, and one which is absolutely diagnostic, is the invasion of the lymph nodes in the axilla. This process takes place very early in the dense fibrous tumors with small cells in distinction to the soft tumors with large cells. The difference seems to be entirely a mechanical one and to depend upon the ease with which the cells are carried by the lymph current.

The second point is the invasion of the lymph channels of the breast by the cells of the carcinoma. This invasion can be easily distinguished from cross sections of the acini by the presence on the walls of the lymph space of the layer of endothelium, which normally lines it. There is also no basement membrane such as is seen in the connective tissue surrounding an acinus.

The third point is in the morphology and arrangement of the cells themselves. The cells of a carcinoma are larger than those of a proliferating gland, the nuclei are larger, the chromatin network is better marked, and division figures can usually be found if the preparation is carefully searched. The cells of the inflamed and hyperplastic glands sometimes extend beyond the line of the basement membrane, but only for a short distance; while in a carcinoma the cells are generally not seen in direct contact with glandular structures, but widely scattered throughout the lymph channels of the connective tissue.

HEREDITARY SYPHILIS.[1]

BY HOWARD S. KINNE, M.D.,
OF NEWBERRY, PA.

An accepted definition of hereditary syphilis is that it is a syphilis transmitted at the time of conception, either through infected semen of the father or an infected ovum of the mother, or through both. The recognition and treatment of this condition are very important from the standpoint of the physician, as much can be done in the way of prevention and treatment, and from the standpoint of the moralist, the sympathy which is called forth by the innocent victim of its progenitors' errors, stimulates us to persevere in our utmost endeavors to help these unfortunate beings.

Usually where syphilis is inherited, it is the eldest child that suffers most, and often it is the first-born only which is affected (this, of course, when the disease is not contracted by a parent after one or more children have been born), showing the lessened tendency to transmit the disease as time goes on. This is a natural tendency and is marked, even in the cases which have not been subjected to treatment.

Hereditary syphilis differs from the acquired form in being constitutional from the first. There is no chancre, nor in the course of its development can the manifestations of the disease be classed under distinct periods for while they may correspond in type to secondary or tertiary lesions, a chronological order, such as in acquired syphilis, is not present. For the first two years or so after birth secondary and tertiary manifestations appear side by side. Later and about the time of puberty, if lesions appear, they belong exclusively to the tertiary type. The local lesions of hereditar syphilis do not differ in themselves from those of the acquired form. The main point of difference between the two lies in the profound alteration which the former impresses on the general nutrition and development—as, for instance, a well-marked case, with its accompanying, always intractable and very often fatal marasmus, or again, in the acute inflammation of the epiphyses and later chronic osteoperiostitis, producing often marked and typical deformity, as, for example, the sabre-blade deformity of the tibia and the nodes upon the bones of the cranium.

In making a diagnosis of hereditary syphilis, the family history is, of course, a most important point, and with this we will have many and varied symptoms and conditions to consider, as is the way with syphilis whenever it occur and however it may be contracted. To enumerate all the symptoms which may appear in cases of this disease would lead us to consider probably every organ and tissue of the body, and would consume more time than is at my disposal.

[1] Read before the North Branch of the Philadelphia County Medical Society, October 8, 1903.

In a case of average severity the child may seem in perfect health at birth, the first definite symptoms making their appearance about six weeks later—these commonly consist of coryza and a quite characteristic erythematous (or, in some cases, papular) rash; the favorite localities being about the anus, genitals, thighs or forehead. The secretion from the nose forms scabs and excoriations, the corners of the mouth become sore and perhaps ulcerated, healing slowly and leaving scars which are carried through life. The mucous membrane of the larynx may become affected, producing a characteristic hoarse cry, and unless the infection is very mild, there is marked anemia and wasting, the skin appearing shriveled and shrunken. The effects of the poison seem very depressing, the digestive organs are interfered with; the infant wastes away and in many cases dies. The mortality is high in those which show a marked syphilitic infection, while, on the other hand, those who suffer in a less severe form, and are early subjected to treatment, gain flesh and improve rapidly, but later, or about the time of puberty, symptoms which correspond to the tertiaries are apt to appear in a more or less severe form.

When the fetus has received a large or virulent dose of the syphilitic poison, or for some reason in the embryonic state, it is more susceptible to the infection, the infant, if born alive, survives but a short time—a few minutes, or perhaps a few days. And so we might cover the entire gamut, from the mildest taint, with only ill-defined and perhaps very late symptoms to the opposite extreme of the malignant form, where the patient is overwhelmed with the poison and cannot survive.

Hutchinson says the diagnostic recognition of hereditary syphilis is a matter of much difficulty in all stages of the malady, and the belief that it is easy leads to constant errors. He says in making the diagnosis it is necessary to have a combination, in a marked form, of snuffles, a ham-colored eruption on certain parts of the body, a general wasting, senile physiognomy, etc., and that none of these alone is of much importance.

While we know this is true in respect to a positive diagnosis, and also that every child which has coryza or a skin eruption is not syphilitic, still I think we are inclined, and properly so, to look with suspicion on any child which has a positive family history in this respect, and which shows even few and rather ill-defined symptoms, and to give them the benefit of antisyphilitic treatment.

As to the subject of treatment, it does not differ in principle from that of acquired spyhilis, but in practice there are some elements which we have not to deal with in adults:

1. *The Matter of Prophylaxis.*—It is well known that the administration of mercurials to the tainted mother while pregnant will very much reduce the chances of the offspring being affected.

2. *The Question of Nutrition.*—This is a very important consideration. It is essential that the diet of these infants be looked after with the greatest care; that they be breast fed, if the mother is able to furnish good milk, and if this is impossible, that their food be adapted with the greatest nicety, and that hygienic rules be observed with the highest possible exactness.

3. *The Manner of Administering Specific Treatment.*—It is unnecessary, and, I think, unwise, to give mercury or iodides unless some symptoms appear. In the early stages, when there are symptoms, mercury should be given by inunction, bichloride baths, or by the mouth, in the form of gray powder, calomel, etc., though I have found the mercury and chalk to be effective and the best tolerated. Later, in what corresponds to the tertiary stage, potassium iodide, mixed treatment, etc., must be resorted to.

I wish to report briefly a case which recently came under my observation, which seems to illustrate a few points in the discussion of inherited syphilis: (1) There were no early manifestations of the disease, only a rather late development of tertiary lesions; (2) the large doses of potassium iodide, which were taken without any difficulty, and (3) the happy effect of medication.

William C., aged six years and nine months; father and mother living and well at present; two brothers, thirteen and twelve, and one sister four years of age. According to the mother's statement, she contracted syphilis from her husband ten years ago; had the usual secondary symptoms and was treated for the same, taking medicine for eighteen months. No marked symptoms since. She had three miscarriages following date of infection, then gave birth to this boy, who seemed in perfect health when born. He was breast-fed for one year, and, except for an occasional cold or some slight ailment, continued well until about January of this year (1903), when he was six years old. He was brought to St. Joseph's Hospital March 10, 1903, and at this time showed a distinct swelling over the middle metacarpal bone of the right hand. This swelling had been noticed about three months and at the time of the examination was seen to be inflammatory in nature, the surrounding skin being shiny, tense and red. The mass pitted on pressure, and there was well-marked fluctuation. There was also a fluctuating gummy mass, non-inflammatory in character, occupying the position of the lower portion of the biceps tendon of the right leg, and seemed to be within the sheath of the tendon. This swelling was painless; the one on the hand was somewhat painful on manipulation. The patient also complained of fugitive pains in the leg and head.

Under an anesthetic the diseased hand was incised and curetted. With the probe necrosed bone could easily be felt, and the probe could be entered into the canal of the metacarpal bone. The wound was given general antiseptic treatment and the boy received alternately, inunctions of mercurial ointment and internally bichloride, gr. 1-24 and KI. gr. v. t.i.d. The potassium iodide was increased ten

grains a week until he was taking 50 grains t.i.d., and he has continued this dose ever since with no signs of iodism and entire disappearance of all symptoms for which he came under treatment. The hand is entirely healed and, except for a little stiffness, he has perfect use of it.

DIFFICULT CASES OF INFANT FEEDING.[1] [2]

BY THERON WENDELL KILMER, M.D.,
OF NEW YORK;
ASSISTANT ATTENDING PHYSICIAN, OUT-PATIENT DEPARTMENT OF THE BABIES' HOSPITAL, NEW YORK; ATTENDING PHYSICIAN, CHILDREN'S DEPARTMENT OF THE WEST SIDE GERMAN DISPENSARY, NEW YORK.

The problem of the artificially-fed baby is usually a complex one. There is no branch of medicine or surgery which is more difficult of comprehension or taxes the resources of the physician more than does the rational feeding of an infant, especially if he comes across that infant after a few weeks or months of improper feeding.

Thinking that perhaps a description of a few of the most common cases of difficult infant feeding which have occurred in my own practice during the past few years might be of interest to the Society, I am induced to write the following paper.

There is all the difference in the world between the way of bringing up an infant at the present time and that of twenty years ago. We have all heard the views expressed by some fond grandmother of the *terrible* way in which babies are brought up nowadays. It is nothing like the good old-fashioned method! This is true, and it is a matter for congratulation that there have been marked changes in the care and feeding of infants from the days of long ago. The dirty-mouthed baby, the foul nipple, the microbic nursing bottle incubators and the cholera infantum milk have all been relegated to the realms of the past. But, surely, notwithstanding the rapid advances made in infant-feeding, the general practitioner is bothered, and bothered as nothing else can bother him, regarding some little patient who has been improperly fed. What, then, are these cases?

A baby is brought into the world, a healthy, normal baby, is started on breast milk, and for a time all goes well. Then the mother's milk gives out, or the mother decides that it would be much less trouble to let her nursemaid attend to the baby's feeding; or, because her infant vomits, he is put on the bottle, the physician never being consulted at all. The average New York mother of the higher class who is perplexed by the servant question, by social duties and strained domestic relations, makes a very poor *cow*. The pace of living is becoming faster and faster, and where our nursing mothers will be in ten years' time, if this hurried, nervous state of living exists, I must frankly confess, I cannot tell. In 99 out of 100 cases, when an infant who has been hitherto unaccustomed to cow's milk, is put for the first time upon that diet, he is given milk far too strong for him. He may grow fat and seem to do well on this heavy food, but he is getting carbohydrates, fats, and proteids enough for a baby of six months; his flesh is flabby and not like the firm, pink flesh of a healthy baby. An early excess of fats and carbohydrates diminishes proteid metabolism, and the crash finally comes. Baby's appetite wanes, he loses weight, attacks of constipation and diarrhea make themselves manifest, and a chronic gastro-enteritis is set up.

Then what occurs? The mother, or nurse, thinks that, as cow's milk does not agree with the baby, other substitutes will be borne better. Condensed milk is now tried. Just as she put the baby on too strong cow's milk, so now she puts the baby on too weak condensed milk. The condensed milk is thrown aside, as it, too, does not agree with her baby. Then begins a continual dietary change, and the poor infant is put through a lightning change of all the patent foods on the market—each with the same result that, when first begun, all seems to go well for a day or so and then the baby goes back to a state worse than at first. As a dernier résort the physician is summoned! He finds himself facing a hard proposition. Here he has a baby with practically a ruined digestion—a proteid digestion practically nil, gastro-enteritis, flabby muscles, slight fever at times, loss of weight, and an alabaster skin. What, then, should be done with a child in this condition? It has been my practice when confronted with a case like this to tell the mother that her baby has been improperly fed and overfed from birth, that it will take a few weeks—in some cases even longer—to get him started correctly and that, unless she places her baby under the care of a trained nurse or else follows directions to the letter, I will have absolutely nothing to do with the case. This is essential in my mind for the proper feeding of such an infant. I have often, in similar cases, where the parents could not afford a trained nurse, been told that the mother did just as I directed, but I knew she did not, as results proved.

Such an infant should have his stomach washed out daily with warm water, especially if there is much vomiting. It is astounding, in this condition, to see the mucus that can be washed away from a baby's stomach. Stomach washing is done by means of a small, soft rubber catheter (20 F.); a connecting tube of rubber and a glass funnel. Also give the baby's bowels a good flushing out, with a decinormal salt solution; use a long, soft-rubber rectal tube. It has been my plan to start these babies on a weak cereal water, such as barley water, for a few days, until their digestive apparatus is in a better condition to assimilate food.

The baby should be weighed every day at the same time, and should be weighed naked. After a few days of this barley water diet, add *one teaspoonful* of cow's milk to one of the bottles of barley water and note the result. Watch the stools for curds. If many curds are present and

1 Read before the Riverside Practitioners' Society.

2 Received for publication April 19, 1904.

if there is much colic, put the baby back on barley water for a little longer. If all goes well, add one teaspoonful of cow's milk to every feeding; then, after two days, add two teaspoonfuls of cow's milk to every feeding, and so on gradually get the baby back to a feeding of which he can take care. Never feed a sick child on a special formula; formulas are for healthy children.

Oftentimes a baby of this class will not be able to assimilate even the smallest amount of proteid, and I do not think that, if a baby has a weak proteid digestion, the addition of barley water to the milk will cause him to assimilate more proteids. This addition of barley water may more finely divide the curd, but if the child can only digest so much proteid, that is all he can digest, no matter in what form or dilution it is given to him. I have seen cases where a baby could not digest cow's milk at all, no matter in what dilution. These milk idiosyncracies are not at all uncommon. Again, we may have a baby with a ruined digestion, and when we proceed to feed this baby with proper food, he will not take it. Let him starve, then, until he does eat, do you say? If you do this, he certainly *will* starve. How are you going to feed this baby and make him drink his food? The food is given to him by gavage. The method is simple and when, after a few times, the baby finds that his stomach is filled whether he likes it or not, he will prefer drinking his meals to having a rubber tube pushed down his throat. Vomiting babies who will retain no food when it is given them by the bottle do well and retain their food when it is given them by means of gavage. A baby may be too weak to take his food in any other way. I have seen many cases of feeble digestion, where a teaspoonful of unsweetened condensed milk to three ounces of water or barley water was assimilated, when no other form of nourishment would be borne.

In some cases feeble digestion begins at birth, but usually the difficult cases which we are called upon to treat are those of a digestion ruined by wrong feeding. Improper nursing from the breast is a great factor in the causation of malnutrition. The mother's milk becomes poor from indiscreet diet, etc., or disease, and, notwithstanding this poor milk, the baby is still fed upon the breast until he breaks down. Breast milk should be frequently analyzed in order to see whether it contains the proper amount of nutritional elements, namely, fat, sugar and proteids.

Other cases of malnutrition are caused by acute illness, such as pneumonia, whooping-cough and influenza. In all cases the problem is the same: to adjust the food to an infant whose powers of digestion and assimilation are very feeble and easily disturbed. We often see babies who are chronic vomiters and are made so by their mothers or nurses jouncing or handling them continually after they have been fed. These babies stop vomiting at once when placed in the hospital.

Proteids are the ingredients which usually cause trouble in artificially-fed babies, and, as I said before, the majority of babies are started on food that is far too rich in proteids. A certain amount of science in the feeding of infants is to be encouraged, but a thoroughly scientifically-fed baby, who has all his food sterilized and put up by men wearing white caps and operating gowns and who are *supposed* to mix fats, proteids and sugar with accuracy (?)—I say that for these *aseptic* babies I have absolutely no use whatever. In a properly constructed home there is surely money enough to buy two quart bottles of eight-cent good milk, a 16-ounce graduate and a few 8-ounce nursing bottles. With these articles and a little time on the part of the mother or nurse, baby's feedings can be made at home with ease and comfort. On the other hand, there are times when laboratory milk is not only useful but of great importance. I speak of cases of improper digestion in babies who of needs must travel, or are at times isolated from a source of good milk supply, or who are in a disease-infected district. In these cases laboratory milk has worked wonders.

Condensed milk is one of the worst curses upon a community of babies. "What is easier," says the young mother, "than by following the directions on a can of condensed milk to rear a big, fat, healthy child? It is absolutely no work at all." A sixteen-cent can of condensed milk in the ice box, or, more generally, in the *bathroom*, a spoon and some water, that is all. Baby, for a time, gets big and fat. He beats all the babies in the block in weight. We have all seen these square-headed, feeble-boned, open-fontanelled, big, fat, rickety babies with a rosary on their ribs that can be seen across the room. "It was no bother to bring *him* up," says the mother. No, her bother has *just begun*.

So much against condensed milk. Now, a word or two for it. It is unquestionably one of the best foods to switch off on if baby's stomach becomes a little upset, as it were, from too much proteid. For a short trip, or in a district where good cow's milk is not procurable, condensed milk answers admirably. Among the poor in a great city in summer many babies would die were it not for condensed milk. The mothers have no means to keep cow's milk, and condensed milk tides many a tenement house baby over a critical heated period.

In closing, let me cite a case which is picked at random from many that I have seen during the past few years. It simply illustrates the average case of disordered digestion from the usual cause, namely, improper feeding.

Case.—A. B., six months old; breast-fed for one month from birth; weight at birth, eight pounds. Both parents healthy. The baby, without the advice of the attending physician, and upon the advice of a nursemaid, was taken from the breast for fear that "he would drain the mother's strength," and was placed upon a mixture of almost pure cow's milk. The baby lost weight, cried at night, had attacks of constipa-

tion and diarrhea and regurgitated his food. The nurse now told the mother that the cow's milk was too strong for the baby and that he must be put on prepared foods. He seemed to improve for a week or two, but went back to his disturbed state soon afterward. One food after another was tried, and all with the same result. The family now thought it high time to consult a physician. The baby presented the true characteristics of an overfed baby. His stomach was washed out, his rectum and colon were flushed, he was put on barley water with a gradual addition of milk, as I have heretofore outlined, and in three weeks one would hardly have known the baby. He has since been well and is now two years old.

What conclusions may we draw, then, from this essay? I think they are (1) The artificial feeding of babies is not the simple and easy problem which some of our lay friends seem to regard it. The physician should be consulted frequently in every case where a baby is fed by either breast or bottle. Every baby is a law unto himself and should be fed as an individual; (2) the general public should be taught that they should not and cannot feed the rising generation of infants on "any old thing," and in any way that they choose. A baby's food should not be experimented with by the laity. It is the baby's life, and parents have no right to trifle with it.

165 West Eighty-fifth Street.

TRANSITION OF OBSESSIONS TO DELUSIONS; WITH REPORT OF TWO CASES.[1] [2]

BY ALFRED GORDON, M.D.,
OF PHILADELPHIA;
INSTRUCTOR IN NERVOUS DISEASES, JEFFERSON MEDICAL COLLEGE; ASSISTANT VISITING NEUROLOGIST TO PHILADELPHIA HOSPITAL; NEUROLOGIST TO DOUGLASS MEMORIAL HOSPITAL.

In physiological life the following fact is very frequently observed: an idea, a sentence, a word or an image may unexpectedly invade our mind and obstinately persist. It is sufficient, however, to exercise our will to a certain extent and make this phenomenon disappear without leaving any trace. This is a *physiological obsession.*

Should this condition persist in spite of the will, or should the will be unable to vanquish the irresistible condition in spite of repeated efforts, the phenomenon will become morbid and we are then in presence of a *pathological obsession.* Here the individual is conscious of the feebleness of his will, he realizes his inability to resist this morbid tendency and his will power is annihilated by the unknown force called obsession. Should he attempt to oppose this force and struggle, considerable efforts will be required of him, emotion and anxiety will set in and he will suffer.

We therefore see that between the physiological and pathological obsessions there is only a question of degree, but there is a certain condition which must be absolutely present for the development of the pathological form of obsessions, namely a special mental make-up which forms the basis of the so-called degenerates. Only individuals with an insufficient mentality, only those whose will-power is compromised or lost, those who show hesitation, timidity or want of determination in every sphere of life, those who are unable to adapt themselves to circumstances, those who become accustomed early in life to introspection and to analyzing their own psychic life, those who show a dissociation of the personality,—these are the individuals of whom Magnan speaks as affected with cerebrospinal ataxia, ataxia of thoughts, sentiments and will, ataxia of the psychomotor functions. The tendency to obsessions forms an inseparable element in these individuals, it is born with them and it remains for a long time in a latent stage. Although the attacks of obsessions are only episodes in the life of the degenerates, nevertheless by virtue of the fact that they are intimately associated with their psychic make-up, one cannot avoid considering them as psychic stigmata of the degenerates. These morbid psychic phenomena, showing some mental disturbance, are nevertheless not true insanities. They are only the expression of a faulty mental equilibrium and their evolution is such that they are constantly threatened with a break. It is, therefore, evident that insanities should be expected in individuals presenting morbid obsessions. We often see cases of mental affections, in which a previous history of various neuroses and obsessions can be traced.[1]

A close analysis of obsessions will show that their immediate cause is the lack of control of the will. The patient preserves his reasoning power, he is conscious of the want of harmony between the will and the inability to remedy the condition. Should this condition persist for a long time and should the patient whose psychic make-up is unstable begin to analyze the obsessions, he is apt to lose all power of critical judgment, become passive, cease to struggle against the overwhelming obsessions; his consciousness, which helped him to struggle, becomes absorbed, and he then accepts the condition as an inevitable phenomenon, finding complete justification for it and ascribing it to some tangible cause. The patient then reaches the final step of the pathological evolution of the obsessions and we are in presence of a genuine delusion.

We mentioned above that there is only a difference in degree between a physiological and pathological obsession. The same difference likewise exists between a pathological obsession and a delusion which developed from an obsession. The analogy which exists between obsessions in general and systematized delusions appeared so striking to Arndt, Mendel and Morselli that with good reason they gave the name of *"rudimentary paranoia"* to certain forms of obsessions.

Cases of insanity with previous obsessions are not at all rare, that delusions may develop in addition to obsessions is also known and that a cer-

1 Read before the Philadelphia Neurological Society, April 26 1904.

2 Received for publication April 30, 1904.

1 See "A Note of Psychoses of Early Puberty." A. Gordon, *Phila. Med. Jour.*, Sept. 6, 1902.

tain obsession by a process of progressive development will gradually become a distinct and well-defined delusion is by no means so unusual as some alienists pretend. According to Séglas, who became interested in the subject in 1889, the transformation of obsessions into genuine delusions affects only the so-called "intellectual obsessions," especially those of doubt or indecision and then the form of persecutory delusions is the most frequent. The delusional transformation of obsessions was observed in confusional insanity, melancholia and paranoia and the origin of it lies in the dissociation of consciousness which exists in a primitive stage in those that are affected with obsessions.

It was the writer's good fortune to have under his uninterrupted observation within the last three years two such cases, and to keep detailed records showing the possibility of such an occurrence. The cases are briefly as follows:

Case I.—H. D., aged twenty-eight years, civil engineer, three years ago began to notice that he had to repeat his prayers in church several times before he could be convinced that no word had been omitted. At first the disturbance was confined only to the church prayers, but three months later the night prayers at home began to disturb him in a similar manner. He worried considerably over it. He would not be able to go to sleep for fear the night prayers were not said by him completely. Then he would have to get up in the middle of the night to repeat the same act. Being perfectly aware of the absurdity of this state of affairs he would make attempts to control himself and resist the overwhelming desire to repeat the prayers. Then he would become agitated, restless, irritable; he would struggle with himself, but finally would have to submit to that great power which had captured his consciousness. After the act of repeated praying was done, he would become calm and peaceful.

Thinking that perhaps the presence of strangers would help him to overcome the irresistible act, he often made appointments with his friends. Before them he would say his prayers in a loud and distinct voice. He was, therefore, convinced that no words were omitted. However, some time after the departure of the guests he would gradually go back to his previous state and would feel gradually coming on the necessity of repeating the act of praying. Again he would struggle and again he would be overpowered. As this obsession at first concerned only the one act of his life, his daily work did not suffer in the least. Once while at work he was suddenly taken with a chill, became covered with perspiration, began to tremble and cry. He felt that on the previous night he did not repeat often enough his prayers and that he must do it now. He kept on crying and struggled with himself, but the more he struggled, the more he suffered. He had to yield. After that he would have to quit his work several times during the day and pray. At first he did it two to three times a day, but later he was compelled to do it oftener. It is, however, certain that this was done every time not without a great amount of resistance on the patient's part, and every time he would pass through a series of nervous disturbances similar to those mentioned above.

The patient's health suffered considerably, as the inability to overcome the obsession had an exhausting effect on him. Headache, anorexia, general weakness in addition to the insomnia, made their appearance. As the condition did not change and the repetition of the above described act became very frequent the patient, although still conscious of its unreasonableness, began to analyze the obsession. He asked himself at first only occasionally and later more frequently the question: Why should he have to pray so often and what is the reason that no other act of his life disturbs him? At this phase of his disease he contented himself with these questions without being able to explain. But afterward he went further and insisted upon an explanation which he gradually discovered. He says: As almost two years have elapsed from the day when the necessity of praying repeatedly came on and as he finds that he must do it now very often, there is certainly some divine reason for it. He is and was most undoubtedly a sinner, said he, and the Lord, who is kind and fatherly, inclined to every human being, necessarily wishes him to be better. This is the cause why He prompts him to pray often.

The patient's wife and relatives attempted to divert his mind from the newly coming thoughts, but without avail. More and more he became absorbed with this irresistible idea of self-condemnation. He considered himself now a religious sinner, he had erred against the Lord, his religious views were not according to the teachings, he was not a good man, he deserved all that had happened or will happen to him.

The delusion was well formed. The patient's life, character and disposition changed entirely. He refused to work, as there is no use, he says, he will die shortly. Spends his time in worrying and complaining of his unfortunate fate. In the intervals he would pray and pray almost constantly for forgiveness. He did not struggle any more with himself, he did not attempt to overcome the desire of praying, he did not question any more the necessity of praying, as the latter was no more an obsession. On the contrary he hurried to pray, fearing he had not done enough of it, because he now wished to redeem himself, to obtain forgiveness for the lack of religious behavior in the past. He is, therefore, totally *delusional*. The patient became morose, would refuse to see his friends or to go out. He would never ask for food, if it was not offered. As the insomnia increased, he was found several times walking in his room and either praying or talking to himself. Sometimes he would be seen with outstretched hands at the window looking in the dark space and talking aloud. He developed visual as well as auditory hallucinations. The patient presents now an averred case of a typical melancholia with systematized delusions and hallucinations.

Case II.—Mrs. A. G., aged thirty-five years, is taking care of a butcher-shop. Her husband, who is alcoholic, very often neglects his work, and she is therefore obliged to work hard. At the age of ten years she had chorea and at fifteen night terrors. She was always considered unusually bright. Two years ago while handling the knife with which she cuts meat for customers, she suddenly felt the necessity of doing some harm with it. She could not tell at the time to whom her desire was directed. Since then this impulse has come on frequently.

At first she felt it when she was using the butcher-knife for business. Later on the same sensation would be present when she even looked at the knife. She was a woman of a mild temperament, charitable and very kindly disposed toward every one with whom she came in contact. She could not understand why she should feel the necessity of using the knife for a purpose other than for business. She reasoned with herself and, being fully conscious of it, she soon began to fear the knife. As she was the only one in the shop to do the selling, she had to use the knife very often. The constant fear, that some harm may be done by her, put her in a state of anxiety which she could not overcome. As soon as the knife was in her hands, she could hardly use it properly, she would make mistakes, would interrupt the cutting repeatedly and before the work was done she would show signs of suffering; her skin at first would be flushed and at the end of the act would be pale and covered with a profuse perspiration. At times she would not be able to finish the work, was compelled to throw the knife under the table and dismiss the customer.

For a long time the patient suffered agonies. She often came to me to seek relief from this torture. She struggled heroically against this overwhelming feeling, but every time she was overpowered. One morning she came to me informing me that she spent the whole night in thinking over the misfortune and that after due consideration she arrived at the conclusion that her husband is the fault of her suffering. He leads a very irregular life, drinks to excess, maltreats her and her trouble is due no doubt to the worriment he brings upon her by leading a life of debauchery. Gradually she fixed her mind upon this idea and all my efforts to dissuade her were of no avail. She was convinced, she says, of the truthfulness of her explanation.

We, therefore, see that the mental analysis of the future delusion began at this phase of the patient's affection. Very soon a new phase made its appearance. She told me that her husband often expressed his dissatisfaction with her appearance and that he regretted having married her. Now, she says, he makes her miserable intentionally, because he wishes to get rid of her. She was taken at first with a dislike to him and soon began to despise him and her children, of whom she had previously been fond. She conceived the idea that her oldest daughter conspired with her husband against her, as she often saw them talking quietly together. She became suspicious, her suspicions being directed even against her youngest child, who was only five years old. She began to watch her relatives, strangers and customers. Once she overheard a conversation between her oldest daughter and a neighbor and immediately became suspicious of the latter.

The idea of using the knife with the intent to do harm did not annoy her any more. She did not suffer, as she did not struggle with herself. Upon being questioned she replied that she feels the necessity of using the knife against her husband, as he deserves it; all, in fact, says she, deserve to be killed, as she is the victim of her husband's persecution and everybody is conspiring with him against her.

Being more and more convinced that he intends to free himself from her and that he fully made up his mind to torture her, so that she may die, she began to take special care of herself. She would see that the door of her room was tightly closed and locked so that he would be unable to poison or shoot her. She would also examine her bed-clothes, the bureau, the drawer in the table. She was convinced that some day some explosive would be put under her bed-clothes by her husband and she would be blown up. At night she would lay awake for hours and at the slightest noise would get up and listen.

Hallucinations soon developed, but curiously enough they were unilateral. It was only on the right side that she would see visions and hear sounds. The latter were of a threatening character: shadows, terrible faces would approach her to the right and curse her. She thought of protecting herself and for this purpose placed in her room pokers, pieces of iron and the butcher-knife.

In spite of all the vigilance on the part of the family, who was constantly warned by me, she succeeded in eluding them. One night her sister, who was placed in the next room to watch her, heard a terrific noise from the patient's room. At once she went there and found her sister armed with a poker in one hand and a knife in the other breaking the bric-à-brac, windows, mirrors, etc., screaming, shouting and threatening. No words could pacify her and force had to be used to remove the knife from her. Upon being questioned she replied that her husband, who is her greatest enemy, sent devils and animals against her in order to get rid of her as soon as possible. At this phase of the disease as well as before the hallucinations set in I insisted upon the commitment of the patient, but was met with great opposition. The family looked at my proposition with great disfavor, as the old view of considering a commitment as a disgrace still persists and is very difficult to combat. The patient was removed from the city and sent to relatives in the South.

The two cases just related appear to me to be highly instructive. The mental analysis and the continuous introspection which gradually led our patients to delusional insanities were exceedingly interesting from a psychological standpoint. We

could see that when the stage of obsessions was overstepped, the mental introspection which is one of the characteristic features of obsessions, gradually vanished, the consciousness of the mental analysis which is always present in obsessions, gradually merged into those mental processes that constitute the approaching delusion: the patient's personality forms then an integral part of the new morbid ideas, they lose all psychic inhibition, and become slaves of their ideas. Then the previous morbid introspection takes a different orientation. The patients commence to find a harmonious connection between the outside world and the world of their imagination. While before they were only observers or witnesses of their obsessions without being able to explain them, now they find logical reasons for their morbid thoughts; absolute conviction takes place of doubts.

The two cases reported here are of interest, not only to the psychologist, who wishes to draw comparisons between mental processes in normal and pathological states, but also to practical psychiatrists. From the latter standpoint the present contribution puts on record cases showing not only the development of mental affections in individuals with neuropathic tendencies, but also the fact that the so-called neurasthenic insanities may cross the border-line and shape themselves into genuine psychopathies. Finally the transformation of obsessions into delusions by means of a gradual accentuation and of a special orientation of the first—is the most interesting and the most important feature of the present essay. Mental analysis, which seems to be the *sine qua non* of progress in the intellectual domain providing the normal intellect guides it and directs it in the proper channel, may become the origin of special pathological phenomena. The comparative study of the physiological and pathological obsessions, also of delusions, shows that they represent various stages of the same mental analysis. The transformation of one form into another depends upon the favorable or unfavorable basis on which they develop. The mental analysis in a degenerate is always a source for various psychic disturbances; at first obsessions, later genuine delusions.
